(Gauthier et al. 1990); Apalachicola Bay, Florida (Fisher et al. 1996); and Tampa Bay, Florida (Fisher et al. 2000). The presence of different size oocysts parasitizing a number of the same oysters at different sites probably indicates a concurrent infection by two different species of this protist. The smaller size oocysts from the Caloosahatchee oysters are probably those of *N. ostrearium* because they are both similar in size (~10 × 14 μm) and are most conspicuous in the mantle and in connective tissue around the digestive diverticula, where *N. ostrearium* are generally found (Sprague 1949, Lauckner 1983). Also, numerous mud crabs *Panopeus* sp. and *Eurypanopeus depressus*, which are the definitive hosts for this parasite (Lauckner 1983), were abundant at all study sites where the protist was observed (Volety et al. 2003a). The larger oocysts are probably those of *Nematopsis prytherchi* because they are similar in size (~19 × 16 μm), occur in the gills, and have been reported to occur concurrently with *N. ostrearium* in *C. virginica* (Sprague 1949, Lauckner 1983). The definitive host for *N. prytherchi* is the stone crab *Menippe mercenaria* (Sprague 1949) which were also found at the Caloosahatchee sites sampled (Volety et al. 2003a). Reports concerning the pathogenicity of *Nematopsis* infections in *C. virginica* are inconclusive but most researchers have found no evidence to indicate the parasite is harmful to oysters (Overstreet 1978, Lauckner 1983).

The cnidarians observed infesting the gills of Caloosahatchee oysters did not seem to cause any pathologic distress to the hosts, even though large numbers of the symbiont were present in many of the collected animals. Several species of warm water hydrozoan cnidarians inhabit body folds of bivalve molluscs as inquiline symbiotes. Of these, only one North American genus, *Eutima*, is found in *C. virginica* attached to the oysters gills, mantle and palps (Mulholland & Fredl 1996, Samler 2001). Those researchers collected oysters from numerous sites along the southern Atlantic and Gulf coasts and observed hydroids only in Florida from Tampa Bay and St. Augustine southward (Samler 2001). Thus, it is probable that the hydroids observed in the Caloosahatchee oysters belong in this group. The light to heavy infestations with no observable pathology detected is not unusual because prior studies of these hydrozoans reported that oysters can tolerate thousands of polyps without apparent harm (Samler 2001). Infestations appeared to have a seasonality because hydroids at those collection sites with the heaviest prevalence were observed in spring and early summer months (February to June) whereas almost none were detected in midsummer through fall. The summer decline was similar to other closely related bivalve-inhabiting cnidarians, *Eugymnanthea inquilina*, observed in mussels and clams from the Ionian Sea, Italy (Piraino et al. 1994) and Japanese waters (Kubota 1983). Kubota (1983) reported a summer decline in hydroids from Japanese waters noting that polyps became very small, and often degenerated, at the end of medusoid production. In addition, Samler (2001) reported hydroid numbers in Florida waters declined rapidly following large drops in temperature or salinity after heavy summer rains. Experiments determined critical temperatures and salinities for these hydroids to be between 10 and 33°C and 8‰ to 34‰ respectively (Samler 2001). A drop in salinity occurred in the Caloosahatchee study sites during the summer months of the study. Salinities, which averaged 31‰ during most of the study, dropped to under 10‰ at most sites and to less than 5‰ for weeks at each occurrence, especially at Cattle Dock and those collection sites close to it, where the hydroids were most prevalent (Volety et al. 2003a, Volety et al. 2003b).

The turbellarians found infesting the gills of Caloosahatchee

oysters elicited a light to moderate hemocytic response from the gills and formed a mucus coat around themselves. However, since the prevalence was low (1% to 4%) and the numbers of individuals infesting individual oysters were few, the worms are probably more commensal than parasitic. Turbellarians are predominantly free-living predators or scavengers but certain members of the order Alveocoels are intimately associated with marine molluscs (Lauckner 1983). Alveocoel turbellarians have been reported in the mantle cavity and on the gills of numerous bivalves in Europe, Japan, North America, and Mexico (Lauckner 1983, Fleming 1986, Brun et al. 1999, Aguirre-Macedo & Kennedy 1999). In the Gulf of Mexico, members of the genus *Urastoma* ("oyster gill worm") have been observed infesting the gills of *C. virginica* from Tabasco State, Mexico (Aguirre-Macedo & Kennedy 1999) and the Mississippi coast (Overstreet, personal communication). These organisms have been reported most frequently as commensals in bivalves, causing very little pathology and no mortalities (Robledo et al. 1994). Brun et al. (1999) have confirmed the turbellarian has a definite attraction to oyster mucus and shows a greater preference for oysters over *M. edulis* and *M. arenaria* in Atlantic Canada. This lends credence to the hypothesis of Fleming (1986) that *U. cyprinae* is attracted to and probably feeds on mucus produced by the oyster's gills.

Previous researchers have suggested that the copious mucous secretions produced by the worms forms a cocoon-like envelope to protect it from unfavorable environmental conditions or the negative effects of the oysters' defensive mechanisms (Bataller et al. 1999, Bataller et al. 2003). The fact that mucus surrounding the helminths, in this survey, was full of oyster hemocytes supports a defensive role for this response because mucous secretions by these worms may immobilize or make it more difficult for oyster hemocytes to attack them. It is well known that mucous production in animals plays an important role in defense mechanisms. For example, mucous secretion in marine fish gills is their chief defense against gill parasites (Khan 1987, Lafferty 1997).

Although the worms did not appear to cause significant pathology in *C. virginica*, studies with mussels, *Mytilus galloprovincialis*, from Spain have shown that *Urastoma cyprinae* causes serious disruption of gill filaments and significant hemocytic infiltration in the affected areas where the worms were found. This physiologic effect combined with large numbers of the flatworm was believed to significantly reduce feeding capacity in infested hosts (Robledo et al. 1994, Brun et al. 1999).

Encysted digenetic trematode metacercariae found infesting the gonoducts of oysters, beyond taking up space and eliciting localized hemocytic responses to necrotic worms, caused no significant damage to the host. These worms belong to a large group of trematodes collectively known as echinostomes. Digenetic trematodes in the family Echinostomatidae use gastropod and bivalve molluscs as intermediate hosts and have a worldwide distribution (Lauckner 1983). Metacercarial stages of this worm have been reported in *C. virginica* along the Gulf Coast by Little et al. (1966, 1969), Winstead et al. (1998) and Fisher et al. (2000). This group of trematodes is recognizable by the presence of a collar of spines around the oral sucker (Cheng 1973). Little et al. (1966) reported the occurrence of encysted metacercariae of another echinostome, *Acanthoparyphium spinulosum*, in the mantle of up to 100% of *C. virginica* collected near Port Isabel, Texas and on the eastern Gulf coast; 90% of oysters from one Tampa Bay, Florida site were reported to harbor encysted metacercariae of an *Echinostoma* sp. in their gonoducts (Winstead et al. 1998, Fisher et al. 2000). The

encysted worms observed in the Caloosahatchee oysters are probably in the genus *Echinostoma* also, because they have the same number of collar spines and were found in the gonadal follicles just like those reported from Tampa Bay. However, unlike the trematodes reported from Texas, the worms from Florida could not be identified to species because infected oyster tissue fed to chicks and ducklings did not develop into fully mature adults (Overstreet, pers. comm.). The metacercariae found in Florida and Texas oysters caused little observable tissue reaction. Even though cercariae of this group have penetration glands and have been reported encysted in the tissues of other marine molluscs (Stunkard 1937, Cheng et al. 1966) they did not penetrate the tissues of the Caloosahatchee oysters. Instead, the trematode only infested the gonadal follicles that are, in essence, an extension of the outer environment. As such, the oysters did not have tissue "infections" and probably did not respond to the parasite because the follicle epithelium was not breached or damaged. It is also possible that the cercariae were induced to encyst before penetrating tissue by the oyster's humoral defense mechanisms. Cheng et al. (1966) reported that sera from oysters *C. virginica* and *C. gigas* could immobilize cercariae of another echinostome, *Himasthla quissetensis*, before they could penetrate their tissues. However, the oysters do respond to dead or dying worms with massive hemocytic reactions (Winstead et al. 1998, Fisher et al. 2000). Oysters, infested with parasites, kept in laboratory aquaria for 2 mo in Texas (Little et al. 1969) and 1 y in Florida (Winstead et al. 1998) contained up to 70% living encysted trematodes, which may indicate the oysters did not detect the worms presence and therefore did not respond. The common life cycle of these parasites involve birds, humans, and other mammals as definitive hosts and a gastropod snail as the first intermediate host. Free swimming cercariae from the snail penetrate and encyst in various bivalves or fish. These second intermediate hosts are then consumed by the definitive host to complete the life cycle (Cheng 1973). There did not appear to be any seasonality of infestation because oysters from Tarpon Bay were observed to have the parasite all months of the year.

Another trematode, *Proctoeces* sp., infesting the gonoducts of the Caloosahatchee oysters were unencysted, caused no pathology, occurred at low prevalences, and were associated with attached hooked mussels *Ischadium recurvum* (Volety, pers. comm.). Unencysted metacercariae of the fellodistomatid trematode *Proctoeces maculatus* have been reported in bivalves from Europe and the Atlantic coast of North America (Stunkard & Uzman 1959, Lauckner 1983). In the Gulf of Mexico the worm has been reported in the gonadal follicles of *C. virginica* from Pensacola Bay, Florida; Mobile Bay, Alabama; and Pascagoula Bay, Mississippi (Winstead & Couch 1981, Couch 1985). The occurrence of unencysted trematode metacercariae in these oysters indicates the worms may be "progenetic" or precocious last-larval stages. The term "progenetic" is applied to sexually mature, ovigerous digenetic trematodes occurring in invertebrates (Aitken-Ander & Levin 1985) which, instead of using a definitive vertebrate host, can abbreviate its life cycle by maturing and completing its life cycle in a single molluscan host. This characteristic of the genus *Proctoeces* (i.e., to be in different stages within a mussel) is well documented and discussed by Cheng (1967). The presence of attached hooked mussels on the Caloosahatchee oysters is significant because sporocysts, cercariae and, progenetic stages of *Proctoeces* have been found in hooked mussels from Louisiana (Hopkins 1954a), Mississippi (Overstreet, pers. comm.), and Texas

estuaries (Wardle 1980). It is possible that the attached mussels on the Caloosahatchee oysters are the source of the trematode and the worm exits the mussel as a cercariae, becoming available to either a definitive fish host or another mussel, and contacting neither, enters the oysters genital orifice by chance. From there it migrates to a gonadal follicle or duct and may either mature and complete its life cycle using the bivalves as surrogate hosts or remain in a metacercariae stage awaiting a mollusc-eating fish (Sparidae or Labridae). It is pertinent to note that pinfish, *Lagodon rhomboides*, and sheepshead, *Archosargus probatocephalus*, were both collected in the vicinity of sampling sites (Volety et al. 2003a). Seasonality of infestation could not be determined due to the low prevalence (<1%) of the trematode.

Branching sporocysts from the trematode *Bucephalus* sp. invaded vesicular connective tissue throughout the oyster and in heavy infections completely destroyed or "castrated" the gonads via mechanical damage. Digenetic trematode infections by the genus *Bucephalus* or "bucephalosis" in *C. virginica* is known to extend from Rhode Island to Texas, but is not continuous throughout this range (Hopkins 1954b, Sparks 1985). *Bucephalus* infections in Gulf coast oysters have been reported from Louisiana estuaries (Hopkins 1954a, Hopkins 1957, Menzel & Hopkins 1955, Turner 1985, Gauthier et al. 1990), Pensacola Bay, Florida (Winstead, personal observation); Apalachicola Bay, Florida (Menzel et al. 1969); and Tampa Bay, Florida (Fisher et al. 2000). Pathology of *Bucephalus* infections in the Caloosahatchee oysters is identical to that described in earlier studies. Trematode sporocysts invade the gonad and, via mechanical pressure, totally disrupt its integrity. Any remaining gametes become degenerate and reduced in size, more by metabolic rather than mechanical damage, resulting in parasitic castration (Sparks 1985). In heavy infections growing sporocysts invade the connective tissue surrounding the digestive diverticula, obliterating the space they normally occupy. Later, sporocysts replace connective tissue in the mantle and invade water tubes of gill lamellae (Sparks 1985). Hemocytic response from the oyster is minimal except when sporocysts become degenerate or die. The end result is almost total replacement of oyster tissue by sporocysts, which in late stage infections probably lead to the death of the oyster, especially in adverse environmental conditions (Hopkins 1957, Sparks 1985). Except for some Louisiana bayous in which Hopkins reported 10% to 25% of oysters with *Bucephalus* infections, all the above studies reported low prevalence of infections (<2%) and the Caloosahatchee oysters were no exception with most sites around 1% and one with 3%. It is pertinent to note that prevalence of *Bucephalus* infections has been reported to be highest in low salinity and lowest in open bays with higher salinity (Hopkins 1957, Sparks 1985). This seems to be the case with the Caloosahatchee oysters; all sites with the infection had lower salinity conditions and higher salinity sites had no infections. This correlation of bucephalosis with lower salinity is probably due to the presumed definitive and second intermediate hosts (the true gar, *Lepisosteus* and mullet, *Mugil cephalus*) preference for lower salinity waters. There did not appear to be a seasonality of infection for any sites where the parasite was found.

Larval cestodes, *Tylocephalum* sp., infected oysters at high prevalences at most stations and caused a severe host response consisting of fibrous encapsulation and hemocytic infiltration to resorb the parasite. Host response was in accordance with the observations of Lauckner (1983) and Sparks (1985). Many of the Caloosahatchee oysters had multiple infections of the parasite. Of

60 infected *C. virginica* inspected by Cake and Menzel (1980), some had as many as 125 worms in their tissues but none were weak or moribund or showed any loss of body weight (Lauckner 1983). The location of encapsulated worms varied but in general they were found in loose connective tissue between the digestive diverticula and the stomach and less frequently in the connective tissue of the gills and mantle. The most common route of infection is through the stomach epithelium and there is no appreciable host response until the cestode gets into the vesicular connective tissue around the stomach, mantle or in the gills (Lauckner 1983). After the parasite gets through the stomach epithelium, connective tissue fibers begin to form around it and capsule formation begins. The end result is a thick intercellular cyst of fibrous material between the vesicular connective tissue and a hemocytic infiltration (Lauckner 1983). Encapsulated worms are gradually resorbed by oyster hemocytes, which probably means that *C. virginica* is not a totally compatible host for *Tylocephalum* (Cheng 1967). The resorption of *Tylocephalum* metacestode larvae has also been reported in other bivalves with the exception of the pearl oyster *Pinctada* spp., which is considered to be the normal intermediate host for *Tylocephalum* sp. (Lauckner 1983).

Tylocephalum sp. acudate glando-proceroids or metacestodes are common parasites in marine mollusks throughout the world (Cake & Menzel 1980, Lauckner 1983, Sparks 1985) and have been reported in *C. virginica* from numerous sites along the eastern Gulf of Mexico (Sparks 1963, Cake 1977, Cake & Menzel 1980, Couch 1985, Fisher et al. 1996, Fisher et al. 2000). Cake and Menzel (1980) reported metacestodes in oysters sampled from 22 of 27 sites between Bay St. Louis, Mississippi and Everglades City, Florida. They reported an average prevalence of 43.5% (range 0% to 100%) infection, which is similar to what other researchers have observed in Gulf coast oysters. Also, it was not unusual to find 100% of oysters infected with the parasite at some sites. The Caloosahatchee oysters also had metacestode infections at all sites and some, especially the higher salinity sites at Tarpon Bay and Greys Reef, had prevalences of up to 90%.

The fact that many individual oysters at the Tarpon Bay and Greg's Reef sites harbored multiple species of parasites indicates a fairly rich diversity of organisms in those areas compared with the other sites. It is pertinent that those sites, where fewer parasites were observed, were closer to habitat that has been severely altered by human activity (freshwater release from Lake Okeechobee, pollution and shoreline disruption). Habitat alterations can lead to decreases in parasitism of a population by eliminating the intermediate and/or definitive hosts the parasites need to complete their life cycles (MacKenzie et al. 1995, Lafferty 1997, Lafferty & Kuris 1999). For example, Burn (1980) observed reduced diversity of species and parasite numbers in fish from Raritan Bay, which was heavily impacted by human activity, compared with Block Island Sound which was less polluted. Snails, *Cerithidea californica*, separated from a marsh by a parking lot and highway were completely uninfected with larval trematodes compared with a 25% prevalence in snails inhabiting the adjacent marsh. The definitive hosts for these, worms and birds, were absent in the cut off marsh area because of the habitat alteration (Lafferty 1997). Thus, a paucity or abundance of parasites, especially helminths, in a target population, in this case oysters, may be an indirect indicator of the biotic diversity in that area. If a host population harbors a large number and variety of parasites, especially metazoan parasites, it is probable that a rich assortment of free living fauna is living in or moving through that area (Cheng 1973). It is important

to note, however, that there are many instances where total numbers of the same species of parasite may increase due to human activities, such as pollution (MacKenzie et al. 1995, Lafferty 1997). For example, increased Trichodinid gill ciliates in fish seems to be correlated with a toxicant's ability to impair mucus production, which is a fishes chief defense against those parasites (Khan 1987, MacKenzie et al. 1995). Therefore, as Lafferty (1997) states "it is important to take into account the relative sensitivities of each group and have a through understanding of the associations

between the wide range of parasites and the impacts upon them" before one correlates anthropogenic impacts with biotic responses.

A REVIEW OF THE MARKET STRUCTURE OF THE LOUISIANA OYSTER INDUSTRY: A MICROCOSM OF THE UNITED STATES OYSTER INDUSTRY

FERDINAND F. WIRTH* AND TARA M. MINTON

Food and Resource Economics Department, Indian River Research and Education Center,
University of Florida, IFAS, 2199 South Rock Road, Ft. Pierce, Florida 34945

ABSTRACT Louisiana enjoys the highest annual oyster production among all states, contributing over thirty percent of the total domestic supply of the eastern oyster, *Crassostrea virginica*. Over the last 2 decades, changes in oyster habitat, concerns over shellfish safety and government regulations have seriously affected the oyster industry in Louisiana and the United States. In an attempt to fill a research void identified by the Gulf Oyster Industry Program, this analysis identifies and assesses the Louisiana oyster industry size and value, product lines, market structure, distribution, and distribution channels. Recommendations to the Louisiana oyster industry include offering an array of value-added products that fit today's busy lifestyle, and addressing safety concerns through quality assurance to restore consumer confidence.

KEY WORDS: oyster, distribution, Louisiana, market structure, value-added products

INTRODUCTION

The eastern oyster, *Crassostrea virginica*, also known as the American oyster, is the principal oyster species being cultivated in the Gulf of Mexico and along the Atlantic coast. In the early 1800s, Louisiana's first commercial oyster operations began in the estuaries near the present Mississippi River Delta. In the mid-1800s, immigrant fishermen realized that high-quality oysters could be produced by transferring small "seed" oysters from the natural reefs near the delta to bedding grounds closer to the Gulf of Mexico. These higher salinity areas did not support substantial natural populations due to high predation, but were excellent for fattening and growth of transplanted seed (Perret & Chatry 1988).

By the turn of the 20th century, Louisiana's oyster-producing areas had been divided into public seed grounds (most productive natural reefs) and private bedding grounds. Public reefs are opened each year in the fall and winter both for collection of seed oysters and harvesting of market oysters. Much of the remaining oyster-producing areas were made available for private leasing. Thus, the basic organization of the Louisiana oyster fishery was established. The state supplied the seed oysters, and the private leaseholders would transfer the seed to their leases for growth to market size. This growout of transplanted seed is a type of oyster production known as on-bottom or extensive culture and is the typical method of farming oysters in the United States today (Supan 2002).

In many ways, the Louisiana oyster industry can be viewed as a microcosm of the entire United States oyster industry, with comparable production and marketing challenges and opportunities. In the last decade, changes in oyster habitat, production technology, concerns over shellfish safety, and government regulations have seriously affected the oyster industry in Louisiana and throughout the United States. High production costs are restricting expansion by established culturists and serving as barriers to entry into the industry. Land for shore-side facilities is in demand by housing, recreational, and manufacturing companies, which can pay premium prices to obtain choice sites. Many coastal activities and competing uses for areas suitable for oyster culture are not compatible with oyster growout procedures.

Determining market characteristics including sale, distribution, and preferred product forms was identified as a major research need by the Gulf Oyster Industry Program (Supan 2000). This report was constructed in an effort to fill this research void, and reports the results of a review of the Louisiana oyster industry's market structure. The analysis identifies and assesses industry size and value, product lines, market structure, distribution, and distribution channels. Key facets of the Louisiana oyster industry are also compared and contrasted with other major oyster-producing states.

INDUSTRY SIZE AND VALUE

World oyster production has increased 10-fold in the last 50 years. In 1950, the United States accounted for 80% of the world oyster supply. By 2000, the United States market share had fallen to only 6%, although the United States landings have remained relatively constant during that time. Figure 1 shows the United States and world oyster landings from 1950 to 2000. The oyster market is currently dominated by China, which supplied 77% of the world's oysters in 2000 (Food and Agricultural Organization 2002).

In 2001, the United States oyster landings totaled 14,800 metric tons (32.7 million pounds) of meat at a value of \$80.9 million (National Marine Fisheries Service 2002a). Figure 2 depicts the United States oyster landings and dockside prices, both nominal and real (in 1996 dollars) from 1974 to 2001 (US Department of Labor 2003). Oyster landings remained relatively steady during this time period; values generally increased until about 1994, after which they tended to decrease. Because nominal prices seem to have increased dramatically across the period, real prices have remained stable. There is a significant negative correlation between the United States commercial oyster landings and real dockside value (Pearson correlation coefficient = -0.418 , $P < 0.05$).

Louisiana currently enjoys the highest annual oyster production, by weight, among all states in the nation, with annual landings generally in the 4,500–5,900 metric ton (10–13 million pound) range. Figure 3 shows eastern oyster landings in Louisiana from 1950 to 2001. As the current production leader, Louisiana contributes significantly to the Gulf and United States supply. During the 5-year period from 1997 to 2001, Louisiana contributed 54% of the total oyster landings in the Gulf Region. At the national level, Louisiana averaged 32% of the total landings during the

Figure 1. United States and World Oyster Landings, 1950-2000.

same 5-year period. In 2001, Louisiana provided 37% of the United States' oyster production with 6,000 metric tons (13.2 million pounds) of meat (Louisiana Department of Wildlife and Fisheries 2002). Over 1,100 Louisiana producers used 170,000 hectares (420,000 acres) to produce over 77,000 metric tons (170 million pounds or 1.7 million sacks) of oysters in 2001 (Louisiana Cooperative Extension Service 2002). In February 2003, there were over 8,500 active oyster leases in Louisiana covering more than 166,000 hectares (409,000 acres) of leased water bottom (Louisiana Department of Wildlife and Fisheries 2003).

The value of Louisiana's oyster industry has been trending upward. Averaging just over \$6.0 million annually during 1961 to 1966, the Louisiana oyster industry reported a farm value of \$20.7 million in 2001 (Louisiana Cooperative Extension Service 2002). Although some of the increase was due to inflation, much of the increase in value resulted from an increase in production and price. The significant, and continuing, decline in the United States and, especially, Chesapeake Bay oyster production since 1981 may have expanded demand for Louisiana oysters. This decline in the United States production is believed to have had a positive influence on Louisiana dockside oyster prices. However, there is evidence that the demand for oysters dramatically declined during the late 1980s and early 1990s, possibly as a result of consumer concerns over product contamination, health, and nutrition (Lipton & Kirkley 1994).

PRODUCT LINES AND PROCESSING

Product Lines

The number of different types of oyster products being produced throughout the United States from the eastern oyster, *Crassostrea virginica*, has declined from 15 unique products in the 1970s to only 6 products in 1991. Products include counter stock half-shell oysters (unprocessed), fresh raw shucked oysters, breaded oysters, canned stews, canned oysters and smoked oysters (Lipton & Kirkley 1994). Oysters currently produced in Louisiana fall under 2 product classifications: raw shucked, and counter stock sold in the shell. Production is largely raw shucked oysters. Counter stock oysters are those of the highest grade, the most carefully cultivated that are served on the half-shell at restaurants and oyster counters.

Value-added Processing

In the United States, processed eastern oysters are almost exclusively fresh, raw product. From 1970 to 1990, the percentage of oysters processed as fresh, raw shucked product increased from 76% to 92%. The only other significant processed oyster product is breaded oysters, which are available fresh or frozen, either raw or cooked. Breaded oyster production fell by one-half from 1970 to 1990, down to less than 726 metric tons (1.6 million pounds).

Figure 2. United States Oyster Landings and Nominal and Real Dockside Values, 1974 to 2001.

Figure 3. Eastern Oyster Landings in Louisiana, 1950 to 2001.

Production of canned oysters and oyster stews from eastern oysters had virtually disappeared by 1990. Stews are increasingly being made with imported oysters. Only one firm reported processing smoked eastern oysters in 1990 (Lipton & Kirkley 1994).

Because Louisiana accounts for about half the annual Gulf region oyster harvest, oyster processing activities in the state are generally well below 50% of the Gulf region total and appear to be declining. Louisiana's share of the Gulf region oyster processing activity has fallen from 38.5% by value during 1971 to 1975 to only 28% by value during the 1981 to 1985 period. No further value-added processing activities beyond shucking, such as bread-ing, were conducted by the 30 Louisiana first buyers interviewed by Keithly and Roberts (1988). An examination of the Thomas Food Industry Register (1995 edition) identified few oyster processors in Louisiana. Only nine companies processed fresh, canned, or frozen oysters. Three companies were involved with private label manufacturing. No Louisiana companies were identified as producing breaded oysters, stew, or chowder.

Keithly and Roberts (1988) offered 3 possible explanations for Louisiana's small and declining share of Gulf region oyster processing activities. First, much of Louisiana's harvest leaves the state to be processed in other Gulf states. Second, "though Louisiana oyster companies do conduct primary processing activities (i.e., the shucking of oysters), they perform very little additional value-added services, such as the bread-ing of oysters." Finally, the declining share could reflect the demise of the Louisiana oyster canning business, which had disappeared by the early 1980s, a victim of canned oyster import competition from South Korea and Japan.

Retail Consumer Products

Five supermarkets in Baton Rouge, Louisiana were surveyed in October 1997, during the oyster season, to identify value-added processed oyster products readily available to consumers. Four of the stores represented large supermarket chains that had extensive fresh and frozen seafood departments, and offered a wide assortment of value-added seafood products. The fifth supermarket was a locally owned, independent supermarket. Oysters were available in 4 product forms: fresh shucked, canned whole, canned smoked, and canned oyster stew. Five Louisiana brands of fresh, refrigerated shucked oysters, packaged ungraded in several different sizes

of plastic containers, were readily available in 4 of the 5 stores. One store offered a brand of Washington State farm-raised fresh oysters. Four brands of canned whole oysters were identified, 2 from California companies, 1 from a New Jersey company, and 1 from a Louisiana company. However, the canned oysters from 3 brands, including the Louisiana brand, were products of Korea. A similar situation exists with smoked oysters, which were available from 6 companies. The products from 5 of the 6 companies, including the Louisiana company, originated in Korea. Only 2 brands of canned oyster stew were identified. One of the stews contained Pacific oysters, whereas the source of the oysters in the other stew was not identified.

The absence of local, further processed oyster products in Louisiana supermarkets mirrors the situation in the Mid-Atlantic states. In March 1999, during the Mid-Atlantic oyster season, three supermarkets in the Newark, Delaware area were inspected to identify local and value-added oyster products. Two of the supermarkets are national chains, and the third is part of a large regional supermarket chain. The results were virtually identical to the situation in the Louisiana supermarkets. The fresh, shucked oysters were harvested locally from surrounding Mid-Atlantic states. No other locally produced value-added oyster products were identified. All value-added oyster products, primarily whole canned and smoked canned oysters, were products of Korea or China. Lipton (1999) confirmed the lack of local value-added oyster products in the Mid-Atlantic region. "Oysters are either being sold in the shell or as raw shucked oysters. I haven't seen any local oysters in the value-added market for years."

DISTRIBUTION CHANNELS

Market Segments

The market for shucked and half-shell Louisiana oysters is primarily domestic, located in coastal states, and segmented geographically by region. Only three Louisiana companies export oysters outside of the United States. The primary market is Louisiana and the surrounding Gulf states. Additional strong markets exist in the Mid-Atlantic states and the West Coast, to fill excess demand created by declining oyster stocks in those regions.

Dealer Numbers and Behavior

As of May 2003, the Interstate Certified Shellfish Shippers List reported 50 shellstock shippers, 48 shucker-packers, 18 reshippers, and 2 repackers as certified dealers in the Louisiana shellfish industry (Interstate Shellfish Sanitation Conference 2003). According to the National Marine Fisheries Service Seafood Processor's Survey, the largest four oyster processors in Louisiana represented over 70% of the state's shucked oyster market in 2000 whereas the top 10 processors represented over 91% of the market (Isaacs 2003).

Keithly and Roberts (1988) surveyed 30 primary dealers to document procurement and marketing activities in the Louisiana oyster industry during the 1985 to 1986 season (September 1985 to August 1986). Figure 4 provides an overview of oyster procurement and product form distribution for the 30 dealers. The dealers reported obtaining nearly 55,000 metric tons (120 million pounds or 1.2 million sacks²) of oysters from independent oystermen or their own leases. The dealers also secured another 11,000 metric tons (24.7 million pounds or 247,000 sacks) from out of state, primarily Texas, and another 10,600 metric tons (23.3 million pounds or 233,000 sacks) from other Louisiana dealers. The dealers had a total of 77,000 metric tons (170 million pounds or 1.7 million sacks) for processing and/or sale. The majority of the total (60%) was resold as sacked oysters. A small amount (7%) was boxed. The final third were shucked and marketed in various sized containers.

Thirty-five percent of the sacked and boxed oysters were directed to in-state markets, whereas the other 65% was directed to out-of-state markets. The majority of these out-of-state shipments were sacked oysters, which were primarily destined for processing plants in Alabama, Mississippi, and Florida. The survey results indicated that 30% to 35% of Louisiana's 1985 to 1986 harvest

was processed out-of-state. Of the shucked product, 58% was directed toward out-of-state markets, while 42% was sold in-state. An unknown amount of the in-state sales may have left Louisiana through secondary outlets and been subject to additional value-added services.

OYSTER MARKET STRUCTURE

Consumption

According to data from the National Marine Fisheries Service report, Fisheries of the United States, and authors' calculations, total US consumption of oysters was over 26,000 metric tons (58 million pounds) and per capita consumption was 0.09 kg (0.20 pounds) of meat in 2001. Figure 5 depicts the US per capita consumption of oysters from 1971 to 2001. Per capita consumption was highest in 1972 at 0.19 kg (0.42 pounds) of meat, and lowest in 1999 and 2001 at 0.09 kg (0.20 pounds) of meat (National Marine Fisheries Service 2002a). Limited evidence cited by Lipton and Kirkley (1994) suggests that the decline in demand for oysters is a result of health/nutrition concerns, product safety, water pollution, economic fraud (adulterated product), and media publicity.

There has been extensive publicity about dangers of consuming shellfish, particularly raw molluscan shellfish. In July 2003, a Louisiana court found a restaurant and the State Department of Health liable for the death of a person who ate raw oysters containing *Vibrio vulnificus* (Florida Department of Agriculture and Consumer Services 2003a). On May 1, 2003, the state of California imposed an emergency regulation limiting importation of summer harvested Gulf oysters to "only those oysters subjected to post harvest treatments that reduce *Vibrio vulnificus* to non-detectable levels will be allowed during April through October" (Florida Department of Agriculture and Consumer Services 2003b). Florida, Louisiana, and Mississippi have challenged this rule, stating that it violates the policies of the Interstate Shellfish Sanitation Conference.

Two post harvest treatments designed to combat *Vibrio vulnificus* and *Vibrio parahaemolyticus* bacteria are currently in use in the Louisiana oyster industry. Ameripure Processing Company, Inc. uses a warm water bath followed by an ice-cold shock bath to reduce the existence of pathogens to undetected levels in raw oysters (Ameripure 2004). No chemicals or irradiation are used. Oysters are sold raw in the shell and must be shucked fresh. The process also reduces aerobic bacteria, which slows the natural rate of spoilage, extending the shelf life of the product (Ameripure 2004).

Motivatit Seafoods, Inc. uses a high-pressure processing technology, Fresher Under Pressure developed by Avure Technologies, Inc. (Motivatit Seafoods Inc. 2004). The oysters are exposed to 45,000 pounds per square inch of pressure for 2 minutes. Much like the Ameripure process, high-pressure treatments reduce harmful bacteria to nondetectable levels and decrease spoilage microorganisms. In addition, when placed under pressure, oysters release their adductor muscle from the valve freeing them from the shell, essentially shucking themselves (Food Engineering 1999). No heat is used in this process.

Determinants of Consumer Behavior

In a nationwide study, Cheng and Capps (1988) found that own price elasticity and household size were generally the key factors in explaining the variation of household expenditures on oysters for at-home consumption. The study measured own-price elasticity of demand, which describes the relationship between price and

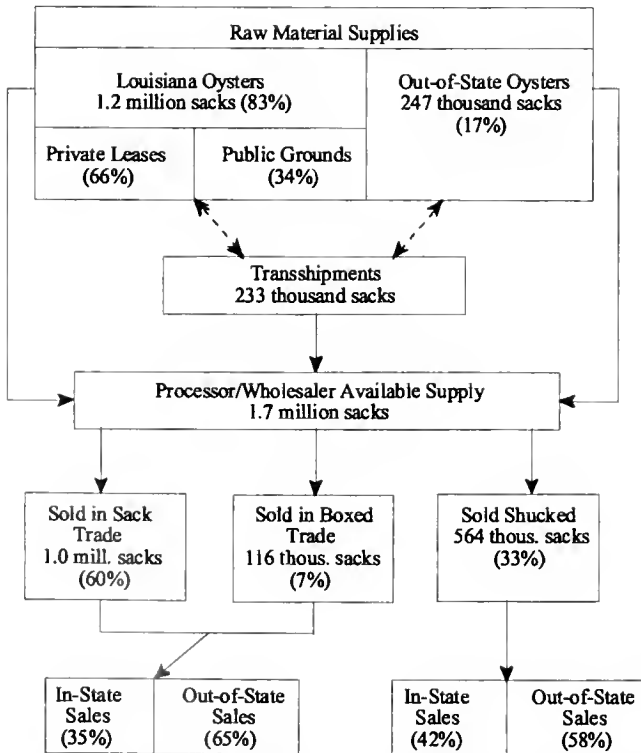

Figure 4. Louisiana Wholesalers/Dealers Oyster Procurement and Distribution Source: Keithly and Roberts, 1988 A sack of Louisiana oysters is 0.045 metric tons or 100 pounds (Keithly 2003).

Figure 5. United States Per Capita Consumption of Oysters, 1971 to 2001.

quantity demanded of a good. They found that own-price elasticity for oysters was statistically significant and had a value of -1.1320 . This means that a 1% increase in the price of oysters would decrease the quantity of oysters demanded by -1.1320% (Penson et al. 2002). The Cheng and Capps' study also measured income elasticity of demand, which describes the changes in quantity demanded of a good based on changes in income. They found household income elasticity of oysters was statistically significant and had a positive value of 0.1769 , indicating oysters to be a normal good. For normal goods, in this case oysters, large increases in income are required to generate substantial increases in consumption (Penson et al. 2002).

Lin and Milon (1993) used a double-hurdle model to investigate whether the decision to consume oysters (participation decision) has determinants different from the frequency of consumption (consumption decision). A rating scale was used to measure perceptions of 5 food attributes commonly cited as the basis for food choices: safety, taste, nutritional value, freshness, and cost. Taste perceptions were highly significant determinants of oyster participation and frequency decisions. Nutrition perceptions were positive and significant in frequency decisions only. Cost perceptions negatively influenced oyster consumption frequency but did not affect oyster participation. Thus, the decision whether to consume oysters was primarily determined by taste perceptions. Once that decision was made, taste, nutrition, and cost perceptions determined consumption frequency. Of the personal characteristic variables, age, gender, and race were significant in the frequency decision for oysters, but only education was significant for oyster participation, with more educated persons being more likely to consume oysters. A similar study by House et al. (2003) found that concern for product safety did not significantly influence whether participants consumed oysters, but did significantly influence the decision of how frequently oysters were consumed. Twenty-five percent of consumers indicated they ate oysters less frequently due to product safety concerns.

Capps and Lambregts (1991) used scanner data to study the demand for fish and shellfish (shrimp, crab, lobster, oysters, and scallops) products in a Texas retail food firm predominantly catering to high-income customers. Own-price elasticity and seasonality were not statistically significant factors in purchases of oys-

ters. Demand for oysters was affected by advertising. Own-advertisement elasticity (0.059) was positive. Cross-advertisement elasticities for finfish (-0.224) and poultry (0.473) suggested that advertisement space for finfish and poultry influences oyster purchases.

Little is known about the at-home demand for specific forms of oyster products (i.e. canned and stews), demand for away-from-home consumption of oysters, or changes in oyster demand over time. Lipton and Kirkley (1994) evaluated the trends in at-home oyster consumption, comparing data from the 1977/1978 and the 1987/1988 USDA National Food Consumption Survey. They found that the share of oyster purchases represented by each of 3 oyster product types (fresh/frozen shucked oysters, canned smoked or salted oysters, and oyster stew) had changed over the 10-year period. The share of fresh/frozen-shucked oyster had decreased only slightly, from 54% to 50%. The share of canned oysters doubled, from 25% to 50%. The share of oyster stew fell from 21% to 0%. The increasing share of canned oysters, combined with a high price for smoked eastern oysters compared with the Pacific oyster counterpart, led Lipton and Kirkley (1994) to conclude that canned, smoked eastern oysters is one product for which "there appears to be wide open market" for oyster producers.

"The changing socio-demographic and economic structure of the US population, as well as changes in consumer lifestyles, has contributed to the increased popularity of food away from home." Nayga and Capps (1995) measured the effect of socioeconomic factors on the probability of consuming fish and shellfish away from home. The findings generally indicated that older people, people with higher income, people with smaller household sizes, and people on a special diet are more likely to eat fish and shellfish away from home. The study recommended that fish marketers and processors emphasize these factors when formulating marketing strategies designed to promote consumption.

Complements and Substitutes

According to Cheng and Capps (1988), the cross-price elasticity (0.1991) between red meat and oysters suggested that red meat and oysters were gross substitutes. Cross-price elasticity between oysters and poultry was not statistically significant.

Capps and Lambregts (1991) found that, in Texas, cross-price effects for other shellfish (1.21) are positive and statistically significant, supporting the notion that other shellfish species (shrimp, crabs, lobster, and scallops) are substitutes for oysters. Cross-price effects for finfish, pork, poultry, and beef were not significantly different from zero.

Domestic Competitors

The major competitor for Louisiana oysters are oysters produced in other regions of the United States. Oysters are harvested in 18 of the 21 contiguous coastal states. Four species of oysters are presently being cultivated in the United States. *Crassostrea virginica*, the eastern oyster, is the principal species on the Atlantic Coast and the Gulf of Mexico, and accounts for most US oyster landings. *Crassostrea gigas*, the Pacific oyster, is the primary culture species on the West Coast and second in volume produced, with approximately 3,600 metric tons (8 million pounds) produced annually (National Marine Fisheries Service 2003). Two species of the genus *Ostrea* are also cultivated at low levels. *Ostrea edulis*, the European oyster, is grown in Maine, and *Ostrea lurida*, the native West Coast Olympia oyster, is the basis for a small industry in the states of Washington and Oregon (Burrell 1985).

The catastrophic decline in natural eastern oyster populations in the Chesapeake Bay left the Maryland and Virginia oyster industries in near collapse. Because the main cause of the historical decline is most likely overharvesting, Dermo and MSX, occurrences caused by parasitic protozoa, have essentially wiped out remaining natural stocks and made traditional culture methods in the region unproductive. Figure 6 shows eastern oyster harvests in Maryland, Virginia, and Louisiana from 1950 to 2001. In Virginia, oyster production peaked in 1958 with 11,800 metric tons (26 million pounds) and has declined drastically ever since, reporting just over 91 metric tons (0.2 million pounds) in 2001. In Maryland, the harvest peaked in 1954 and again in 1973 with 9,000 metric tons (20 million pounds). The Maryland industry produced 590 metric tons (1.3 million pounds) in 2001 (National Marine Fisheries Service 2003).

Other species of bivalves, including clams, mussels, and scallops also compete with Louisiana oysters for market share. The main non-oyster bivalve competitor is the hard clam, *Mercenaria mercenaria*, which is widely distributed throughout the Atlantic and Gulf of Mexico coastal waters, and has long supported a major commercial fishery in the New England and Mid-Atlantic coastal

states. US cultured clam output was 4,900 metric tons (10.7 million pounds) in 1999, with a reported value of \$42.0 million. On the top ten US seafood list for the last decade, per capita consumption of clams was 0.22 kg (0.49 pounds) in 2000 (Johnson 2001).

Imports and Exports

The United States imports, largely from the Asian region, are principally low-value canned or smoked oysters. Imports were high in 1987 at 23,600 metric tons (52.0 million pounds), however they declined to 12,500 metric tons (27.5 million pounds) by 1990 (Lipton et al. 1992). In 2002, US oyster imports totaled 8,700 metric tons (19.1 million pounds) worth \$36.9 million (Economic Research Service 2003). Imports of fresh and frozen oysters accounted for approximately one-third of total oyster imports in 2002, whereas canned oysters accounted for the remaining two-thirds imported for consumption (National Marine Fisheries Service 2002b). The United States exports far fewer oysters than are imported. Oyster exports in 2002 totaled 1,800 metric tons (3.9 million pounds) with a value of \$8.7 million (Economic Research Service 2003). The United States oyster exports are comprised of fresh and frozen product; no canned oysters were exported by the United States in 2002 (National Marine Fisheries Service 2002b). Because little of the United States oyster harvest is canned, the degree of competition between imports and Louisiana oysters is debatable. In a survey of United States oyster wholesalers by Lipton and Kirkley (1994), 44% of the Louisiana dealers believed imports posed a problem for increasing domestic sales.

CONCLUSION

This analysis has identified and explored several key issues that the Louisiana oyster industry must confront and solve to assure future industry growth and success. There seems to be room for expansion in the United States and Louisiana oyster-processing sector, especially value-added services such as breaded or smoked oysters. There are now basically only 2 eastern oyster products, whole oysters and fresh-shucked oysters. As oyster production increases through industry revitalization efforts and aquaculture production, new product forms will have to be developed (Lipton & Kirkley 1994). Expansion of the processing sector will generate increased oyster industry revenues through time. Other value-added shellfish products (especially shrimp and clams) have been created for the institutional trade and as convenience items for home use. Specialty products such as soups, stews, and breaded

Figure 6. Eastern Oyster Landings for Selected States, 1950 to 2001.

oysters prepared for institutional service would take advantage of the increase in the number of people eating out. Consumer preference studies may provide direction for product development (Supan 2000).

Oyster processors wishing to exploit value-added product opportunities should follow the example of Tallmadge Brothers Inc. of Connecticut, which added to its product line of oysters, clams and shucked meats by investing in a blast freezer and introducing individually quick frozen half-shell oysters and clams on vacuum pack trays. Tallmadge's Marketing Director provided the rationale for the new product introduction by stating that "to penetrate the retail sector we are going to have to find a way to make clams and oysters accessible to today's busy two-income family" (Rheault 1997).

Finally, efforts to combat the market impacts of shellfish contamination, through harvesting regulations and innovations in post harvest treatments, must continue. Studies of consumer attitudes

toward different oyster quality assurance processes may shed light on the relative market merits of the different techniques. Oyster quality assurance may very well be the marketing key to restoring consumer confidence in Louisiana oysters.

REPRODUCTIVE BIOLOGY OF THE "COPEY" SNAIL *MELONGENA MELONGENA* (LINNAEUS, 1758) IN CISPATÁ BAY ON THE CARIBBEAN COAST OF COLOMBIA

SANDRA HERNÁNDEZ¹ AND WOLFGANG B STOTZ²*

²Universidad Católica del Norte, Casilla 117 Coquimbo, Chile, wstotz@ucn.cl

ABSTRACT The reproductive cycle of the "Copey" snail *Melongena melongena* at Cispatá Bay was examined from October 1998 to September 1999. Gonad maturation was studied through macroscopic and microscopic observations on the gonads of females >70 mm (total shell height), showing that individuals were mature throughout the year, but with a period of maximal maturity in March which coincided with the time of maximum recruitment. The mean size at first maturity was 52 mm for males and 65 mm for females. A small number of intersex individuals (4%) (masculinized females, with a normally developed ovary and a rudimentary penis; feminized males with a normally developed testis and gonopore) occurred at intermediate sizes. The proportion of males in the population decreases with the increase in individual size, with only females present at the biggest sampled size-class (mean size of 98.5 mm shell height), suggesting protandric hermaphroditism. If this is proven to be true, artisanal fishing preferring larger animals, could severely interfere in the success of reproduction.

KEYWORDS: Reproductive cycle, *Melongena melongena*, Caribbean, protandric hermaphroditism, intersex..

INTRODUCTION

The "Copey" snail *Melongena melongena* (Linnaeus, 1758) is widely distributed in the Gulf of México, the Caribbean and the Antilles. The snail lives on the shallow areas of coastal lagoons, mangroves and estuaries, being an important component of the fauna on soft or muddy bottoms. The snail tends to concentrate on areas with high densities of its prey, which are bivalves, other gastropods, ascidians and carrion (Hathaway & Woodburn 1961, Hawkins 1973, Rodríguez 1976, Flores 1980, Cosel 1986, Morton 1986, Dalby 1989, Villareal 1989, Bowling 1994). Considering this behavior, fishers sometimes use mangrove roots, covered with the mitilid *Mytilopsis sollar* as bait, letting the snails aggregate on the bait from one day to the next. The method of collection of these snails includes walking over the bottom and locating the snails beneath the mud with the foot. By doing this, the fishers are not able to discriminate size, all sizes being fished. *M. melongena* attains sizes up to 200 mm of shell height (Clench & Turner 1956, Abbott 1974, Flores 1980, Díaz & Puyana, 1994). In Cispatá Bay individuals between 12 and 151 mm shell height are found, the mean size of capture being 57 mm.

M. melongena copulates from December to July in Colombia (Rodríguez 1976) and then produces egg capsules. Egg masses of *M. melongena* have a common basal layer. The number of capsules produced fluctuates between 27–31, located along a string which measures up to 218 mm in length. Some modified, sterile egg capsules are produced and serve to anchor the egg mass on the soft bottom. This sterile capsules are smaller than fertile capsules, but have the same shape and are spaced approximately 28 mm apart at one end of the string. The average distance between fertile capsules along the string is only 6 mm, this distance getting shorter towards the last capsules produced. Egg masses are mostly buried in soft bottoms close to the vegetation on the coast. The capsules contain at least 185 to 290 embryos according to D'Asaro (1997), or 300 to 400 embryos according to Flores (1980), each embryo measuring 250 to 300 µm. The development within the capsules takes 20 to 25 days. By day 16 a well developed veliger larvae is observed, having four large velar lobes with a double row of strong

cilia on their outer edges. The foot and operculum are well developed, the larvae apparently being able to crawl. By day 25 or older, when removed from the capsule, the larvae no longer protruded the velar lobes, but they crawl actively and could rapidly turn over the shell with the aid of the foot. When the capsules open, most of the young snails, now incapable of swimming, immediately crawl and appeared to be feeding (Clench and Turner 1956)

Rodríguez (1976) reported that the smallest mature females found in Cartagena Bay measured 80 mm and the males 65 mm of shell height. Besides this observations by Rodríguez, information on the gonad maturation of *M. melongena* in Colombia is scarce.

With few exceptions, prosobranch gastropods are gonochoric, typically with internal fertilization, although some species demonstrate protandric hermaphroditism (Gallardo 1989). Rodríguez (1976) identified *M. melongena* females with shell heights between 40 and 62 mm having an incipient development of the penis. Species related to *M. melongena*, such as *Busycon carica* and *M. corona*, have similar characteristics (Castagna & Kraeter 1994, Zetina 1999).

Previous observations have suggested that in nursery habitats, small individuals were mostly males and in areas where growth and maturation occur, larger individuals were predominantly females (Hathaway & Woodburn 1961, Woodbury 1986, Zetina 1999). Intersex individuals and sex dominance in different size categories, suggest that *M. melongena* may be a consecutive protandric hermaphrodite. This requires verification, since artisanal fishing activities, which prefer larger sizes, may negatively affect the population by seriously altering sex proportions. The fishery for *M. melongena* occurs throughout the Caribbean, but as the snail is only used for local consumption, it does not appear in the statistics. Nevertheless, the fishery is important, for example Hernández (2001) estimating for the Cispatá Bay area (the bay and nearby sloughs) that 70% or the total biomass of the snail population is fished, representing for local fishers ca. 30% of their total income. The meat of the snail is mainly used around the Caribbean to offer appetizers (the popular "botanas") in beach restaurants of tourist areas.

The objective of the present study was to describe the reproductive cycle and pattern of recruitment, sex ratio and the presence of intersex individuals in *M. melongena* in Cispatá Bay. This in-

*Corresponding author: wstotz@uch.cl

formation should provide a base for fisheries resource administrators to design biologically sound management measures for this resource.

MATERIALS AND METHODS

Study Area

Individuals of *M. melongena* were collected from October 1998 to September 1999 from the Cispatá Bay area (includes the nearby sloughs and the area close to Amaya Beach) (Fig. 1).

Reproductive Cycle

Each month from October 1998 to September 1999, snails were searched for in the field (as fishers do, with the foot), collected manually and measured. This sampling was part of a study regarding distribution, abundance and growth of the snail. Thus, a great number of individuals (over 100), representing the entire depth distribution, was sampled. For the study of the reproductive cycle the largest 30 females, but measuring at least 70 mm of shell height (females of that size were observed to lay eggs), were selected. Due to the fishery, in which the average size of capture is around 50 mm, with few individuals reaching 80 mm or more, large individuals are scarce in the field, so when ever possible, larger individuals were bought from fishers. To get the 30 females, collected individuals had to be sacrificed to verify sex. As the aim of the study was to know the time of reproduction of *M. melongena* in Cispatá Bay, the analysis was concentrated on females, considering that only when they are mature, copulation can occur. As perhaps not all females, but probably all males, may reproduce each year (as described for other gastropods), this method may sub estimate the number of reproducing individuals within the population. But the general seasonal pattern will not be affected by this.

The tissues of each measured individual (total shell height in mm), were removed, and the gonad separated from them. Each component was then weighed separately (drained wet) to the nearest 0.01 g. The gonads were fixed in Bouin's fluid and prepared using traditional histologic procedures to obtain thin sections (6 μ m) stained with Ehrlich's Haematoxylin and eosin. Three sections were taken from each embedding block, each 360 μ m apart to avoid including the same reproductive follicles in the different sections.

Two methods were used to establish the reproductive cycle. The first included a macroscopic quantitative evaluation (gonad index = GI) and the second was based on microscopic qualitative evaluation (index of gonad maturity = IGM).

The gonad index (GI) is represented by:

$$GI = (\text{weight of the gonad} / \text{total weight of tissues}) \times 100$$

For the total weight of tissues all soft tissues of the animal, including head, foot with operculum, visceral mass, mantle, as well as the gonad, were included.

The index of gonad maturity (IGM) characteristics were established for each stage of gonad development, as defined by Ramorino (1975):

- Evacuated (I): walls of acini with a corrugated appearance and abundant phagocytes within them.
- Maturing (II): internal walls of the acini with pedunculated and pyriform vitellogenous oocytes and the presence of a few phagocytes and large spaces between them.
- Maximum maturity (III): the walls of the acini take on a po-

lygonal form without spaces between them and the presence of abundant nutritive cells.

IGM was calculated using the following equation:

$$IGM = (\sum (n \cdot F) / N) \times 100$$

Where F = stage of gametic development (I–III), n = number of individuals in stage F and N = number of total individuals.

Recruitment

Using the size frequencies obtained throughout one sampling year and the growth parameters calculated by Hernández (2001), the FISAT program routine for recruitment patterns (Gayaniño & Pauly 1997) was used. This permits determination of the number of recruitment pulses per year and their intensities. For this study, recruitment was defined as the addition of new individuals into the benthic population.

Mean size at first maturity

Based on information reported by Rodríguez (1976) and Flores (1980), which describe that *M. melongena* copulates from December to June, the egg masses being most abundant in February and March, an intensive sampling was done between December 1998 and March 1999. Ten individuals were obtained for each 10 mm size class, beginning with 20 mm individuals. This number of individuals was decided, considering the possibility to really obtaining them in the field, or being able to buy them from fishers. The lower limit of 20 mm corresponds to the smallest individuals fishers include in their catch. Both males and females were identified, using histologic sections of the gonads. Individuals were rated as either immature (abundant connective tissue; absence of, or very few acini), or mature (Stages I–III). The data for each sex were fitted to a logistic model using the CurveExpert 1.3 program (Copyright (c) 1995–1997 Daniel Hyams.) based on the equation:

$$Y = a / (1 + e^{-cx})$$

Where Y = Relative accumulated frequency (%), a = constant, b = slope, c = constant and x = total shell height.

The mean size at first maturity was estimated at a level of 50% of the relative accumulated frequency (Zetina 1999).

Sex ratio and Intersex individuals

Through macroscopic and microscopic observations, individuals were identified as either males or females and thereby an estimate of the sex ratio was obtained. When sex determination between macroscopic and microscopic examination did not agree, individuals were classified as in the intersex phase based on criteria used by Reed (1993) and Zetina (1999). At the macroscopic level, masculinized females present an atrophied penis which was smaller than that of normal males. An ovary was observed at the microscopic level. The feminized male had a gonopore with no macroscopic differences from that of a normal female, and microscopically they have a testis.

RESULTS

Cispatá Bay (Fig. 1) is located in the Department of Córdoba, on the Caribbean coast of Colombia, between 9°26' and 9°21'N and 75°54' and 75°45'W. The bay is located south of the Gulf of Morrosquillo. It has an irregular topography, is bordered by mangroves, and has estuarine waters with a mean depth of about 2 m.

Figure 1. Map of Cispatá Bay and related inner and outer (coastal) sloughs on the Caribbean coast of Colombia.

(Sánchez *et al.* 1997). Inland from the bay occur 12 sloughs which connect with it by channels (Fig. 1).

The study area experiences four climatic seasons including, (a) the dry season from January through March, (b) transition to the rainy season from April through August, (c) the rainy season from September through November and (d) transition to the dry season in December. These seasons are affected by the Caribbean Current which flows from east to west and by the Darien Countercurrent, or Panama Current, which flows northward along the coast (Ramírez 1994). The tides are semidiurnal, with an amplitude of less than 1 m; the annual mean temperature is 26.7°C and the annual precipitation is between 900 and 1200 mm (Patiño & Flores 1993).

Reproductive cycle

A high proportion (>50%) of mature individuals (Stage III) were observed from January through September, except for the months of February, April, and June in which the proportion diminished (Fig. 2). Each peak of mature individuals was preceded and followed by maturing individuals (Stage II). Spawned individuals (Stage I) appeared almost throughout the year, with the exception of January and the period of August and September. Thus, spawning appears to occur between February and July, and

Figure 2. Variation in the Gonad Maturity Stages (see text) of *Melongena melongena* females in Cispatá Bay.

then again in October, the month in which the greatest proportion of spent individuals appeared.

The index of gonad maturity (IGM) increased from October to December, staying high for the rest of the year, but with smaller peaks in January, March, and August (Fig. 3). The gonad index (GI) showed March, June, and September as months with maximum gonad development (Fig. 4). Main reductions in the gonad index, suggesting spawning, were observed during October–November and March–April, and a smaller one in June (Fig. 4).

Recruitment

The recruitment pattern, estimated using the growth parameters $L_{\infty} = 163$ mm and $K = 0.2$ y^{-1} estimated by Hernández (2001), shows that individuals entered the population throughout the year with a maximum in March (Fig. 5). This coincided with the period of maximum maturity, according to the proportion of individuals in Stage III and highest IGM (Figs. 2 and 3). Recruitment throughout the year coincides with the observation that mature individuals occur for the entire year, existing no defined seasonal pattern of reproduction. A small peak was observed in March.

Mean size at first maturity

According to Figure 6a, 50% of males reached sexual maturity at 52 mm shell height; such results fit the logistic model. It was thus estimated that all males were capable of reproduction at a size of 73 mm (Fig. 6a). Data for females also fitted the logistic model. Females became sexually mature shortly after the males at a shell height of 65 mm, with all females capable of reproduction at 77 mm (Fig. 6b). Spawned females 74–75 mm in height were identified in April.

Sex ratio

The sex ratio changed with age (Fig. 7). In the smallest size class (26.5 mm) females predominated, but only 8 individuals of that size class were examined. In the second analyzed size class (32.5 mm) males predominated and then tended to decline toward greater size classes (32.5–92.5 mm). In the greatest analyzed size class (98.5 mm) only females were found, but again, it was only a small sample (4 individuals) (Fig. 7).

Intersex individuals

Few individuals (13) could be classified as in the intersex phase, representing only 4% of the 325 individual examined. Individuals with both male and female characteristics had both a

Figure 3. Variation in the Index of Gonad Maturity (IGM) of *Melongena melongena* in Cispatá Bay.

Figure 4. Variation in the Gonad Index (GI) for female *Melongena melongena* ≥ 70 mm in shell height in Cispatá Bay.

gonopore and an incipient penis similar to normal males, although microscopic examination confirmed they were females (masculinized females) with normal developed ovaries. These individuals measured 40–70 mm in shell height (Table I). Microscopic observations confirmed that some individuals with a gonopore were males (feminized males), and these were 55 to 73 mm in shell height presenting a normal developed testis. All these individuals were classified as in the intersex phase.

DISCUSSION

The coincidence between the major recruitment pulse and the maximum maturity, described by various methods (stages of maturity, IGM, GI) with also coincident results, suggest that the reproductive cycle described is reliable. While the peak of maturity occurs in the dry season, the presence of mature individuals throughout the year shows that variation between dry and rainy season seems to affect little, supporting a hypothesis of continuous reproduction and recruitment, a condition common in neotropical gastropods (Weber 1977). Rodríguez (1976) reported that in another area of the Caribbean, copulation by *Melongena melongena* occurred between December and July. These observations may have been biased by the methodology used by Rodríguez as they were based only on field observations where sampling days did not necessarily coincide with days when ovicapsules were present.

Continuous spawning, beginning at early age, represents a favorable condition for *M. melongena*, which is subjected to an artisanal fishery. According to growth data (Hernández 2001), *M. melongena* becomes sexually mature in its third year (at sizes

Figure 5. Temporal pattern of recruitment into the population of *Melongena melongena* in Cispatá Bay and related sloughs.

between 52 and 65 mm). Nevertheless, the fishery is capturing individuals as small as 12 mm shell height, the main captures occurring from >40 mm, with an average size of 57 mm (Hernández 2001). Thus, most of the fished snails have not reproduced prior to capture. This is a situations which needs to be revised and regulated to prevent overfishing of this resource, af-

Figure 7. Sex ratio (%) of *Melongena melongena* in relation to size in Cispatá Bay. The x-axis shows the mean total shell height of each size class (mm). Numbers above columns represent the total number of individuals analyzed.

fecting recruitment and thus population renewal. That is unless the fishery is inefficient, and a great proportion of individuals of all sizes escape capture.

As *M. melongena* appears to be gonochoric, the observation of intersex individuals generates doubts. The presence of such individuals confirms the observations of Rodríguez (1976), which, in agreement with the present study, reported masculinized females as occurring at sizes between 40 to 62 mm in shell height. For comparison, both feminized males and masculinized females were found in Cispatá Bay, at a shell height range of between 40 and 73 mm.

The decrease in the number of males with increasing size suggests the occurrence of consecutive hermaphroditism. Dominance by females is however frequent in populations of gonochoric molluscs, and becomes accentuated with increasing age, eventually generated by differential mortality (Fretter & Graham 1962, Gibbs *et al.* 1987). It has been found in populations of *Nucella lapillus*, affected by imposex, that the males are more abundant than females, as the latter suffer heavy mortality (Gibbs & Bryan, 1986 and Gibbs *et al.* 1987). But the identification of intersex individuals also points to the occurrence of hermaphroditism. This may however, be due to other specific causes such as those cited by

Reed (1993) who indicated that sexual alternation in *Strombus gigas* could be due to abnormalities in the sex chromosomes. Horiuguchi *et al.* (1994) established that in neogastropods the development of male sex organs in females (termed "imposex") was a broad-scale problem described for numerous species. Gibbs *et al.* (1987) established that the presence of masculinized females in *Nassarius obsoletus* and *Nucella lapillus* could be produced by exposure of these species to toxic compounds present in antifouling paints such as tributylene and TBT (tributyltin chloride). Exposure to these pollutants of females of these species destroys the oviduct, suppresses oogenesis, and results in the development of a testis. The females become unable to reproduce and the population declines as a result (Gibbs & Bryan 1986). According to Horiuguchi *et al.* (1994), the degree of imposex in *Thais clavigera* and *T. bronni*, as indicated by the length of the penis, provides a rough estimate of TBT levels in the environment.

Event though, the change in sexual proportion with size and the existence of few intersex individuals suggests the occurrence of protandric hermaphroditism in *M. melongena*, the evidence is weak. If the occurrence of protandric hermaphroditism is true, however, the fishery for *M. melongena* may be interfering seriously with reproduction, as the individuals are not allowed to reach the larger sizes. This needs to be further studied, following over time the same individuals, to determine if changes in sexual proportion with size and intersex individuals are really evidence of protandric hermaphroditism, or result from other causes.

ACKNOWLEDGMENTS

We are grateful to Hanne Cogolio and Jesus Cantillo for help in field sampling, and to the snail collectors, especially "Tanque". We are also thankful for logistical support provided by Luz Marina Arias, Chief of the INPA office in Cordoba, and to Evila Jarava Ossa for her collaboration. Further thanks are extended to the personnel of the Amaya Research Station, to Marisol Romero of the U.Catolica del Norte, Coquimbo, for guidance in the histological interpretation of *M. melongena* gonads and to Piedad Victoria for review and edition of the Spanish text of this MS. We add final thanks to Adriana Zetina, Cristian Aycaguer and C. D'Asaro for sending reprints of their research which were important to our preparation of this MS. Two anonymous reviewers are acknowledged for their comments, which helped to improve the manuscript.

ABSTRACT The growth and survival rate of wild and cultivated abalone juveniles (*Haliotis fulgens*) transplanted into the sea was measured from January 2000 to January 2003 in Bahía Tortugas, Baja California. A total of 306 wild individuals (17–90 mm shell length) and 529 cultivated juveniles (16–49 mm shell length), were tagged and released in the intertidal zone. Six surveys were carried out during the experiment. The recaptured organisms were released, each time, in the same place once the shell length was recorded. Growth data were fitted to Gompertz growth model. Mortality rate was estimated through an exponential decay model. The growth rate 1 year after release was 52.4 mm/year for wild abalone and 48.1 mm/year for cultivated abalone. In the third year these rates decreased to 30 and 28 mm/year respectively. No significant difference was found. Gompertz equation parameters were very similar for wild ($L_0 = 2.34$, $G = 4.30$; $g = 0.827$) and cultivated abalone ($L_0 = 2.14$, $G = 4.38$; $g = 0.812$). Natural mortality rates were $M = 1.20$ y^{-1} for cultivated juveniles and $M = 0.87$ y^{-1} for wild juveniles. No significant difference was found between both. Sighting efficiency rate was: 74% for both types of juveniles. This proportion is indicative that wild and cultivated juveniles had a similar dispersal and cryptic ability. We conclude that annual survival rates: 30% for cultivated juveniles and 42% for wild juveniles could be sub estimated.

KEY WORDS: growth, survival, transplanting, juveniles, Baja California, *Haliotis fulgens*

INTRODUCTION

Fishing of abalone (*Haliotis* spp.) is one of the leading economic activities in the regional economy of Baja California. Native populations of this mollusk have undergone a sharp decline in numbers since the 1970s, as a result of increased fishing pressure as well as possible climate changes (Guzmán del Prío 1992, 1994). Commercial landings and biomass are estimated to have declined in some areas to one-tenth of their original numbers, in comparison to the 1950s (Guzmán del Prío 1992, 1997).

The outplanting of hatchery-reared abalone for the purpose of restocking natural reefs has been practiced routinely in Japan (Kojima 1995, Seki & Tanaguchi 2002). Recently, successful seedings experiments have been conducted in Australia (Dixon et al. in press). These countries have also been interested in promoting the sale of cultivated abalone in international markets.

In Mexico, the fishing cooperatives of Baja California maintain abalone hatcheries for the specific purpose of restocking their reefs. Similarly, they occasionally transplant wild juveniles from "stunted stock" areas to banks known for their "good growth." To date, however, both practices have lacked the follow-up that might allow assessment of the survival of the seeded stock as well as of its impact on the total biomass of the wild populations. Although data exists on the growth of adult *Haliotis fulgens* Philippi 1845 and *Haliotis corrugata* Gray 1828 (Marín 1981, Turrubiates 1989, Shepherd et al. 1991, Guzmán del Prío & Lopez-Salas 1993), little is known of the juvenile stages of these species.

The purpose of this study is to determine the growth rate and survival of wild and cultivated abalone juveniles following their release at sea, to evaluate the impact of enhancement programs on wild populations of these mollusks.

STUDY AREA

The study was done in the rocky intertidal zone of "Varadero" at Clam Bay (27°37'11"N and 114°50'38"W), a small cove

located southeast of Bahía Tortugas (Fig. 1). The study site is a low-relief shelf with many imbricate rocks sheltered from the dominant northwest winds. Juveniles of *H. fulgens* are abundant in this location.

METHODS

A total of 835 juveniles of green abalone (*Haliotis fulgens*), 529 cultivated and 306 wild, were tagged. Cultivated juveniles ranged in size from 16 to 49 mm length, with a mean of 23.5 mm, and were 1 year old. Wild juveniles had a broader size range, from 17 to 90 mm (mean 53.5 mm), which is approximately equivalent to 1 to 2 years of age.

The wild specimens were captured at sites near Bahía Tortugas and taken to the laboratory in ice chests containing water and giant kelp (*Macrocystis pyrifera* (L.) Agardh 1820). They were measured and tagged along with the cultivated individuals that were obtained from the Aquaculture Unit of Cooperativa Bahía Tortugas. All specimens were allowed to rest for 24 hours in tanks with running seawater to cull damaged individuals.

Numbered polyethylene ribbon tags (Hallprint, South Australia) were fixed to the shells with cyanoacrylate glue (Three Bond TB-1747). Specimen length was measured to the nearest millimeter with vernier calipers.

A random mix of wild and cultivated juveniles was released at low tide in January 2000. In one case, the specimens were attached by hand to the underside or side of boulders, 30 × 60 cm on average, covered in the upper surface by calcareous or foliose algae, but with smooth undersides. Juveniles were planted at densities of 4 to 7 per boulder, according to the microhabitat observations of Carreón-Palau et al. (2003). In another case, 25 to 30 juveniles were placed in 30-cm long, 4-cm diameter PVC tubes in the laboratory, then taken to sea and deposited in cryptic locations among the rocks to allow the specimens to abandon the tubes gradually and choose suitable sites.

The release area was marked off by two 25-m long steel chains placed at right angles to the shoreline and separated from each

Figure 1. Study area.

other by a distance of 75 m. Each chain was also marked at 5 m intervals with small plastic chains as reference points. The seeding and recapturing area was approximately 200 m².

Recaptures were undertaken in summer and winter months, six in total, from June 2000 to January 2003, recording the size and tag number of each specimen. Searching was done always on days when the tide was at its lowest, starting with the release sites and their surrounding area and applying a constant search effort of six people for 1 hour. However, because summer ebb tides (June to July) were not enough to leave the boulders totally exposed, and in addition, a heavy *Macrocystis* canopy is characteristic of this time of the year, the searching efficiency was seriously affected. Thus, we decided to use for the final analysis only the winter data surveys, when we found the lowest tides and less densities of macroalgae cover.

Most recaptured juveniles were measured *in situ*. When this was not practicable, the specimens were carefully detached to avoid excessive handling. After measurement, they were replaced on the rock, making sure they were attached to it.

The data of the mean length by age of recaptured specimens, both wild and cultivated, were fitted to Gompertz growth model (Rawlings 1988, Ricker 1975),

$$Lt = L_0 * e^{G(1 - e^{-gt})}$$

Where:

L_0 = the initial SL at time t_0 ,

G = the instantaneous growth rate at time t_0 , and

g = describes the rate of decrease of G .

Both, cultivated and wild mean length-increments, were compared by ANCOVA test (Scheffler 1980).

To estimate survival, the raw data for the total number of wild and cultivated specimens recaptured each year was corrected as follows: tagged specimens not sighted before the second and/or third recapture were considered to be survivors in the previous periods. This correction allowed us to obtain a more accurate estimate of minimum survival.

The proportion of individuals not sighted before, but sighted in

subsequent surveys was used to estimate the sighting efficiency (Dixon et al. in press). An Arcsine transformation (Krebs 1999) was used to normalize proportions prior to calculate sighting efficiency.

The corrected abalone counts were fitted to an exponential decay model (Rawlings 1988, Gulland 1975) to estimate the instantaneous rate of natural mortality (M) after seeding, from January 2001 to January 2003. An ANCOVA analysis was run to compare statistical significance of the wild and cultivated slopes (Scheffler 1980).

RESULTS

To be able to compare growth and survival estimates in both populations, in the case of wild abalone only specimens whose initial size range was between 17 and 34 mm SL ($n = 112$; mean length = 24.8 ± 0.87 mm) were considered in the analysis. We assumed this range included individuals approximately 1 year old, as in the case of the cultivated specimens which size ranged between 16 to 34 mm length ($n = 520$; mean length 24 ± 0.33 mm). Figure 2 indicates the size-frequency distributions of the wild and cultivated specimens used for the analysis.

Growth

Figure 3 shows the mean annual growth of wild and cultivated juveniles of *H. fulgens*. In general, both groups attained 147 ± 8 mm in length 3 years after release. Because juveniles were released when they were 1 year old, at 4 years both populations were

Figure 2. Size frequency distribution of the wild and cultivated juveniles abalone (*H. fulgens*) selected for analysis.

Figure 3. Mean annual growth of wild and cultivated juveniles of *H. fulgens* after seeding. Year 0 correspond to the start of the experimental period.

virtually ready to recruit to the fishery, which has a commercial minimum size of 145 mm for *H. fulgens* (Ortiz-Quintanilla & Carballo 1988).

The growth rates observed in the first year following release (at age 2 y) were 52.4 mm/year in wild juveniles and 48.1 mm/year in cultivated juveniles. These rates decreased to 29.8 and 28.1 mm/year, respectively, in the third year following release (at age 4 y) (Fig. 4). No significant difference was found between the average growth of the wild and cultured abalones ($F_{(0.05,1,3)} = 0.3633$, $P < 0.0001$).

The following equations indicate the fit of the data to the Gompertz growth model

$$Lt = 2.34 * e^{4.30(1 - e^{-0.827 * t})} \quad \text{for wild abalone}$$

$$Lt = 2.14 * e^{4.38(1 - e^{-0.812 * t})} \quad \text{for cultivated abalone}$$

Both equations look similar and the small differences observed are not significant, as ANCOVA showed in growth rates comparison (Fig. 4).

Survival

Taking into account the total number of recaptured specimens over the 3 years of the experiment, 81.6% on average were recap-

Figure 4. Annual growth rates of transplanted juveniles of *H. fulgens*.

tured once (81.8% wild and 81% cultivated), 17.2% twice (13.6% and 19%, respectively) and only 1.1% of specimens were recaptured on all three occasions (4.5% and 0%, respectively).

The number of tagged empty shells recaptured over the course of the study was very small. Tag-induced mortality or stress involved only 2 organisms 24 hours after tagging. Six months later two other empty shells were found, but these were attributed to predation.

All the recaptures of tagged specimens were found in cryptic locations. In general, specimens showed limited dispersal over the first year, the maximum magnitude of movement with respect to the release area being 2 to 4 m. Dispersal rose slightly in the second year, from 4 to 7 m, whereas by the third year, some specimens were found to have migrated up to 15 m beyond the site of their initial release. At 1.5 years after the start of the experiment, three specimens turned up in commercial catch about 50 m away from their release sites, at 3 m or 4 m depth. This suggests that as the experiment proceeded some specimens moved gradually toward deeper water. Because the search area was restricted to the lowest tide line, individuals that may have moved into the subtidal zone, like those turning up in commercial catch, would not have been recorded.

Table 1 shows the total number of recaptured abalone, including sighted and not sighted ones, after seeding in January 2000. Based on these figures the estimated values of sighting efficiency rate were: 74.2% for cultivated and 74.3% for wild juveniles.

The rates of natural mortality, calculated after seeding, from January 2001 to January 2003, were $M = 1.20 \text{ y}^{-1}$ for cultivated juveniles and $M = 0.87 \text{ y}^{-1}$ for wild juveniles (Fig. 5). ANCOVA test indicated no significant difference between the 2 mortality rates ($F_{(0.05,1,3)} = 0.0185$, $P < 0.0001$). Mortality values converted to annual survival rates were $S = 30\%$ for cultivated juveniles and $S = 42\%$ for wild juveniles.

DISCUSSION

Growth

The mean increments observed 1 year after release (48 mm in cultivated specimens and 53 mm in wild ones) indicate a high rate of growth for this species. In exceptional cases, some specimens showed increments higher than 90 mm after the first year following release.

These values exceed previous growth estimates (35 mm/year) reported for 2-year-old *H. fulgens* juveniles in the area of Bahía Tortugas (Turrubiates 1989). In experiments involving the tagging of individuals larger than 80 mm, Shepherd et al. (1991) found increments ranging from 10–40 mm/year. These growth rates are similar to those reported by Guzmán del Prío and Lopez-Salas (1993) for this same species in Bahía Asunción: 10 to 45 mm/year for abalone larger than 70 mm in length.

The rapid growth observed for both cultivated and wild specimens in the Clam Bay area may be explained by the fact that this site is an optimal habitat for this species, offering a broad availability and abundance of suitable food algae. On the other hand, the intertidal shelf where the experiment took place is of low relief and has many overlapping rocks favoring entrapment of *Macrocyctis* and other drift algae which are easily transported to the hollows and crevices formed by the juxtaposition of rocks in this area (Carreón-Palau et al., 2003). Japanese workers have observed large clusters of *Haliotis* at depths where drift algae are abundant, and high densities of juveniles in shallow habitats with

TABLE 1.

Survey Date	Cultivated Juveniles			Sighting Proportion	Wild Juveniles			Sighting Proportion
	Sighted	Not Sighted	Total		Sighted	Not Sighted	Total	
Jan. 2001	48	19	67	0.72	15	8	23	0.65

Jan. 2003	4	2	6	0.67	3	1	4	0.75

pebbles (Inoue 1973, Kojima 1974, cited by Seki & Taniguchi 2000).

The observed growth rates, along with the existing data on maturity and fecundity of this species (Guzmán del Prío 1992, Gluyas-Millan & Talavera-Maya 2003), allow us to estimate that recruitment to the adult stock could take place at age 4 years, (i.e., when specimens attain a mean SL of 145 mm). Based on this, the 1-year-old juveniles currently being seeded on natural reefs may be expected to enter the fishery 3 years later. However, it should be pointed out that it would be safer for the fishery, to capture abalone equal to or larger than 160 mm SL (Shepherd et al. 1991), because although *H. fulgens* shows the first maturity signs since 105 to 115 mm (García Juárez & Ortiz Quintanilla 1992, Guzmán del Prío et al. 1980, Martínez 2003), catching *H. fulgens* bigger than 145 mm will be assuring several spawning events have taken place and with higher fecundity levels too (Martínez 2003).

Survival

The mortality values obtained in this study of 0.87 y^{-1} for wild juveniles and 1.2 y^{-1} for cultivated abalone fall well within the range from 0.2 to 4.6 for different species, reported by Shepherd (1998). Because we do not have accurate measurements of the proportion of the seeds that moved out of the area, these values might be better considered as a disappearance rate, which includes mortality and migration.

The equivalent annual survival rates for these values: 30% for

Figure 5. Mortality instantaneous rate of wild and cultivated transplanted juveniles of *Haliotis fulgens*.

cultivated abalone seeds and 42% for wild abalone, represent the minimum survival estimates and is likely to be an underestimate because, as we said earlier, we neither have data of juveniles moved away nor enough extra data as empty shell or broken shell collections of the reef that could adjust our estimates. This scarcity of empty or broken shell collections during the surveys could be explained by our 6-month-apart surveys (shells mean half-life is 48 days, as occur in other species like *H. laevigata* [Shepherd 1998]), which made it difficult to find them.

The survival estimates obtained in these types of tag-recapture experiments tend to be biased, because they are affected by diverse factors: some mortality due to the deleterious effect of the type of tag, disturbance as a result of handling during seeding and recapture, and the fact that abalone tend to disperse when disturbed (Day & Fleming 1992, Officer et al. 2001). A further source of bias is the error as a result of low effectiveness in the search of tagged specimens (Shepherd & Breen 1992).

In our experiment, the negative effect of the tags was kept to a minimum by fixing them to the shell without affecting the respiratory pores or other structures. Nevertheless, despite the small number of empty shells recaptured (only 2), we do not rule out the possibility of some mortality being induced by seeding and subsequent recapture.

One of the major concerns was the effectiveness of searches. In our case, the sighting efficiency may have been diminished by the difficulty of turning over large-sized rocks. Despite the fact that the juveniles were seeded on movable rocks, the search had to be extended to the largest possible number of neighboring rocks, including some which were difficult to move. On the other hand, despite the care taken in moving the rocks, each search operation probably caused some dispersal of tagged specimens and an indeterminate number of them may have escaped our sight within the release area.

Another factor was the algal cover, mainly *Macrocystis* canopy, which was very thick at times and made thorough searching in certain areas difficult, particularly in summer. Hence, for the final survival estimates we have used only the annual data for each winter.

A salient fact in the experiment was the vast capacity for dispersal and crypsis shown by both wild and cultivated juveniles. It is well known that juvenile abalone are highly mobile and cryptic (Roger-Bennet & Pearce 1998). At the start of the experiment, most specimens were sighted near the release site, but as time went on it was observed that some of them (Shepherd et al. 1991) and other species moved into deeper water (Tarr 1995).

The fact that 3 adult-sized specimens (2 cultivated and 1 wild) turned up in commercial catch (1.5 years after released) indicates that some tagged specimens moved beyond the original seeding area. Using this data to get some value of the migration rate, we estimate 0.4% for cultivated and 0.8% for wild abalones. However,

these proportions hardly could be considered representative of the real migration rate values, because the specimens appeared only by chance in the commercial catch and not after an addressed survey.

Laboratory experiments have shown that wild juveniles are better able to find cryptic shelter and avoid predation than cultivated juveniles (Tegner & Butler 1989, Schiel & Weldon 1987 cited by Roger-Bennet & Pearce 1998). We did not find this difference. The sighting proportion showed almost identical values (74.2% and 74.3%) for both kind of juveniles.

We suppose that by extending the experiment period to 3 years, the probability of dispersal increased and the likelihood of sighting an indeterminate number of specimens therefore declined. Thus, the survival values reported in this study may actually be underestimates and suggest the need to perform further experiments with a different experimental design to estimate more accurately how many disperse out of the search area.

One of the major concerns of juvenile abalone seeding programs that aim to enhance the numbers on natural reefs is to increase survival and minimize production cost (Tegner & Butler 1985). Efforts to rebuild depleted or declining abalone stocks have been a concern of abalone-producing countries for several years and have furthered work on the transplanting of laboratory juveniles in Japan (Kojima 1995), the United States, (Rogers-Bennett & Pearce 1998), New Zealand (Sweijd et al. 1998), and Australia (Dixon et al. in press). In some cases, there have been transplants with relative success (Kojima 1995, Dixon et al. in press, Schiel 1993) but nevertheless, most attempts have had poor results to date (Withler 2000, Tegner & Butler 1985).

In our case, even admitting the possibility of error due to underestimation, our results do not hold out great expectations for programs aimed at recovering currently depleted stocks. We believe that at least hundreds of thousands of seeds, more than 25 mm, would have to be planted to maximize survival by seeding more robust individuals (Sweijd et al. 1998, Inoue 1976, cited by Kojima 1995). This action could ensure that a greater number of survivors impact on the production in later generations leading to

an increase in biomass; however, the production cost rise with age at release (Sweijd et al. 1998). In addition, we must consider the effects of the sudden introduction of a large number of juveniles, which may not necessarily result in increased biomass, because these specimens may be subjected to competition or predation through density-dependent predation (Hilborn 1998, cited by Shepherd et al. 2000). In other instances, they may produce an aggregative numerical response in predators (Dajoz 1996, Smith 1996), because of the number of prey, in this case the seeded juveniles, increases (Shepherd et al. 2000).

On the other hand, as long as the genetic structure of *Haliotis* populations and how it is affected by massive introductions of hatchery-reared juveniles is not well understood (Withler 2000), and whether the seed will promote recovery of stocks, it will be difficult to achieve success in attempts to enhance or recover depleted stocks. However, this issue is really beyond the scope of this study.

Therefore, at the present time, it seems that in view of the cost, and uncertainty about the benefits offered by seeding, it is wiser to manage existing populations sustainably. This involves an understanding of metapopulation structure of exploited population and requires minimum adult densities in the region. About this, Shepherd and Partington (1995) suggest for Australian waters minimum densities of 0.2–0.3 adults/m² in source habitats, but we still should determine our own figures.

ABSTRACT The karyotypes of 2 northeastern Pacific abalone species, *Haliotis fulgens* and *H. rufescens*, were evaluated from trochophore larvae cells, finding that for both species the diploid number is 36. There were differences between the two species in karyotype according to centromere position classification. *H. fulgens* karyotype was composed by 10 pairs of metacentric, 3 pairs of metacentric-submetacentric, 4 pairs of submetacentric, and 1 pair of submetacentric-subtelocentric chromosomes, and *H. rufescens* karyotypes by 8 pairs of metacentric, 6 pairs of metacentric-submetacentric, 3 pairs of submetacentric, and 1 pair of submetacentric-subtelocentric chromosomes. The relative length of chromosomes 1 to 18 was not different between the species, but 5 of their chromosomes (numbers 4, 7, 9, 11, & 18) were significantly different in relative lengths of short and long arm and in centromeric index, differences that can be explained by pericentric inversions. These observed differences in karyotype between the two species support the previous contention of evolutionary divergence by lysine studies. The chromosome number of the two species evaluated was the same than that reported for other abalones distributed in the northeast Pacific (*H. cracherodii*) and other abalone species distributed in the west Pacific (*H. discus*, *H. gigantea*, and *H. madaka*), although as between these two species, the karyotype of those previously described was also different.

KEY WORDS: chromosomes, karyotype, centromeric-index, relative-length, arm-ratio, Haliotidae

INTRODUCTION

Abalones grouped within the genus *Haliotis*, Linnaeus 1758, comprise from 60 to 70 species described worldwide (Lindberg 1992). They are distributed in the northeast Pacific, northwest Pacific, tropical west Pacific or Indo-Pacific, southwest Pacific, and Mediterranean Sea (Lindberg 1992, Lee & Vacquier 1995).

Karyotypes in abalones have been studied only for few of those 60 to 70 described species. Those species include *H. cracherodii*, from the northeast Pacific (Minkler 1977) with a diploid chromosome number $2n = 36$; *H. discus*, *H. discus hannai*, *H. gigantea*, and *H. madaka* from the northwest Pacific (Arai et al. 1982, Nakamura 1986, Wang et al. 1988, Okumura et al. 1995 in Okumura et al. 1999, Miyaki et al. 1997, Miyaki et al. 1999, Okumura et al. 1999) with a $2n = 36$; *H. varia*, *H. planata*, *H. diversicolor aquatilis*, *H. diversicolor diversicolor*, *H. ovina*, and *H. asinina* from the Indo-Pacific or tropical west Pacific (Nakamura 1985, Nakamura 1986, Arai et al. 1988, Jarayabhand et al. 1998) with a $2n = 32$; and for *H. mberculata* from the Mediterranean Sea (Colombera & Tagliaferri 1983, Arai & Wilkins 1986) with a $2n = 28$. The knowledge of karyotypes in abalone species could provide useful information for systematics of abalone species, and also with a tool to determine the most adequate species for hybridization. Hybridization has been reported to occur among abalone species within certain geographic areas (Owen et al. 1971, Leighton & Lewis 1982, Koike et al. 1988, Hoshikawa et al. 1998), and it represents a potentially important tool for genetic improvement of abalones.

In this research, we aim to define the karyotype of two abalone species distributed in the northeast Pacific, green (or blue) abalone (*Haliotis fulgens*) and red abalone (*Haliotis rufescens*). The karyotypes for these species have not been described, but it was previously reported that both hybridize (Leighton & Lewis 1982).

MATERIALS AND METHODS

For both species, adult abalone was induced to spawn at 2 different abalone hatcheries. For red abalone, 8 cultured organisms at the commercial laboratory "BC Abalone" in Eréndira, Baja California, Mexico were used, and for green abalone 8 wild adults kept at the Laboratory of Abalone Spat Production from "Cooperativa de Buzos y Pescadores" at Isla Natividad, BCS, Mexico. They were induced to spawn, eggs fertilized, and the first hatching trochophore larvae were collected for this study. For both species, only spawns that produced normal and viable larvae were used to collect samples.

Miyaki et al. (1997) procedures for treating larvae and making slides were used. In short, colchicine (0.1%) was applied to the larvae for 2 h, applying a hypotonic shock with sodium citrate (1%) immediately after for 40 min. Larvae were fixed in Carnoy solution, exchanging this solution 3 times every 15 min. Slides were made by placing 50 to 100 larvae on a clean slide, adding 2 drops of cooled acetic acid (60%), macerating with a surgical knife to obtain a cell suspension, and dropping on this cell suspension from a height of 10–15 cm Carnoy solution to expand the macerated cells on the slide. The slides were heated and allowed to dry for approximately 1 h before staining with Giemsa (10%) for 10 min.

Chromosome counts were done at 100X using an Olympus BX41 microscope. A total of 59 metaphases and 60 metaphases were counted for red abalone and for green abalone respectively.

Karyotypes and quantitative measurements of chromosomes for both species were done using the best 10 metaphases obtained from each abalone species. Each metaphase was selected from different slides to guarantee they were derived from different larvae. Each metaphase was digitalized using a Cool SNAP-Pro (Media Cybernetics) camera, and transferred to an image analyses program (Image-Pro Plus 4.5 Program). Measurements of short and long arms of each chromosome, and mean relative length (RL) of chromosomes were estimated according to Thiriou-Quévieux

* Corresponding author: E-mail aibarra@cibnor.mx

(1984), and centromeric indices (CI) and long and short arms relative lengths (LA, SA) based on Levan et al. (1964). Classification of chromosomes was done using centromeric index according to Levan et al. (1964), using conventional names (m for metacentric, sm for submetacentric, st for subtelocentric). Those chromosomes whose mean CI fell within the limit of different types of chromosomes were classified as intermediates between the 2 classes (i.e., m-sm & sm-st). The fundamental number was estimated as White (1973), assigning the value of 4 to all metacentric, submetacentric, and subtelocentric chromosomes, and a value of 2 to telocentric pairs.

Chromosomes comparisons between the two species were done by means of a karyo-ideogram (Spotorno 1985), plotting the relative length of the short versus the long arm with their confidence intervals ($n = 10$, $\alpha = 0.05$).

RESULTS

From the 60 metaphases evaluated for *H. fulgens*, 85% had a diploid chromosome number $2n = 36$, and for the 59 metaphases in *H. rufescens* 61% a $2n = 36$ (Fig. 1).

The karyotype and a representative metaphase from which they were compared for each species are presented in Figure 2a (*H. fulgens*) & 2b (*H. rufescens*). For *H. fulgens* the relative length of the largest chromosome was 7.14 and that of the smallest chromosome was 4.45. For *H. rufescens* the relative length of the largest chromosome was 6.71 and that of the smallest chromosome was 4.48 (Table 1). The fundamental number for both species was 72.

Based on the karyo-ideogram, the karyotype of *H. fulgens* (Fig. 3) can be classified as consisting of 10 pairs of metacentric chromosomes, 3 pairs metacentric-submetacentric, 4 pairs submetacentric, and 1 pair submetacentric-subtelocentric (tending to subtelocentric because of its confidence interval). No telocentric chromosomes were observed. The karyotype of *H. rufescens* is different than that in *H. fulgens*, because it consists of 8 pairs of metacentric chromosomes, 6 pairs metacentric-submetacentric, 3 pairs submetacentric, and 1 pair submetacentric-subtelocentric. As with *H. fulgens*, no telocentric chromosomes were observed for *H. rufescens*.

The analysis by the karyo-ideogram comparing relative lengths of short and long arms, and an analysis of chromosomes differences in centromeric index between the two species indicated con-

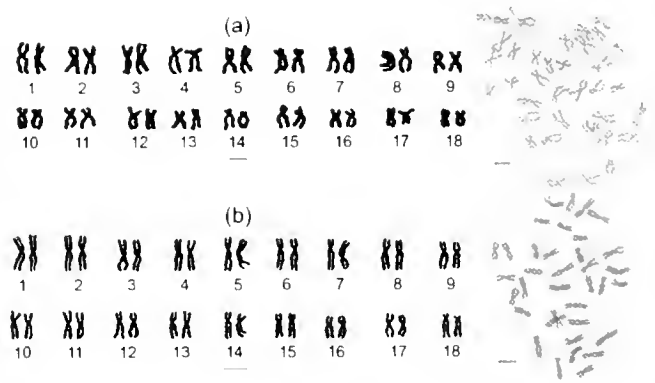

Figure 2. Karyotypes of *Haliotis fulgens* (a) and *Haliotis rufescens* (b), and metaphases used to obtain karyotypes. The bar represents 5 μ m.

sistent significant ($P < 0.05$) differences in relative lengths of short and long arms and in centromeric index between 5 of the 18 chromosomes (4, 7, 9, 11, & 18). Other chromosomes differed in CI or in one or other of the arms lengths, but not in all three (Table 1, Fig. 3).

DISCUSSION

From the abalone species for which karyotypes have been published, the smallest diploid number has been $2n = 28$, followed by an intermediate diploid number of $2n = 32$, and the largest diploid number reported being $2n = 36$ (Table 2). The diploid number of abalone species for which chromosomal studies have been done follows a pattern associated with the geographic distribution of the species (Nakamura 1986), with a $2n = 28$ seen for the Mediterranean species *H. tuberculata* (also named *H. lamellosa*), a $2n = 32$ being present among species of the Indo-Pacific or tropical west Pacific, which includes *H. varia*, *H. planata*, *H. diversicolor aquatilis*, *H. diversicolor diversicolor*, *H. asinina*, and *H. ovina*, and the largest $2n = 36$ seen for species described for the northeast and northwest Pacific, as *H. madaka*, *H. discus*, *H. gigantea*, *H. discus hanaui*, and *H. cracherodii* (Table 2).

Based on genetic studies, today it is believed that not all those described abalone species are different. For example, lysine cDNA sequence homology among 27 *Haliotis* species has indicated that some of the described abalone species around the world are, in fact, the same species (Lee & Vacquier 1995). Species that are possibly a single one and are included in Table 2 are, for the Pacific northwest *H. madaka* and *H. discus hanaui*; for the Indo-Pacific *H. diversicolor supertexta* and *H. diversicolor aquatilis*; and from the Mediterranean *H. tuberculata tuberculata* and *H. tuberculata lamellosa* (or *H. lamellosa*). Two additional genetic studies based on isozyme analyses have also suggested that *H. madaka* and *H. discus* are the same species (Hara & Fujio 1992 in Lee & Vacquier 1995), and that *H. diversicolor diversicolor* is different from *H. planata* and *H. varia* (Arai et al. 1988). Differences in karyotypes seem to confirm that *H. madaka*, *H. discus* and *H. discus hanaui* are the same species, and that *H. diversicolor diversicolor* is different from *H. planata* and *H. varia* (Table 2).

The diploid chromosome number, $2n = 36$ of the two species evaluated in the present study, *H. rufescens* and *H. fulgens*, is in agreement with the previously reported karyotype for only one species from the northeast Pacific, *H. cracherodii* (Minkler 1977), and the reported association between the diploid number with geographic distribution (Nakamura 1986). In as much as the northwest Pacific (Japan) abalone species also have a diploid number of 36,

* indicates that the chromosomes between the two species are different in SA, LA, and IC. Different letters between species indicate significant differences based on confidence intervals ($P < 0.05$). m, metacentric; sm, submetacentric; st, subtelocentric.

our results confirm that marked differences in karyotypes do exist between northwest and northeast Pacific abalones. Northwest Pacific abalones only have metacentric and submetacentric chromosomes, whereas northeast Pacific abalones have those types and additionally have intermediates between those types, and two (Minkler 1977) telocentric pairs of chromosomes, or one submetacentric-subtelocentric in this study. The importance of defining chromosome types as intermediates between two classes comes

from different conclusions reached in different studies for the same species. For example, northwest abalone species described for northwest Pacific are very homogeneous in number of metacentric and submetacentric chromosomes, with most reports indicating that there are 10 pairs of metacentric and 8 pairs of submetacentric chromosomes in *H. discus* (*H. discus discus*, *H. discus hannai*, and *H. madaka*), and *H. gigantea* (Arai et al. 1982, Okumura et al. 1995 in Okumura et al. 1999, Miyaki et al. 1997, Miyaki et al. 1999). However, there are also two reports (Wang et al. 1988, Okumura et al. 1999) indicating 11 pairs of metacentric and 7 pairs of submetacentric for *H. discus* (*H. discus hannai*). The differences reported for *H. discus* (*H. discus hannai*) have been attributed to three pairs of chromosomes (4, 9, and 17) that have arm ratios close to the limits of the classification between metacentric and submetacentric (Okumura et al. 1999), resulting in ambiguous classification even within which today is believed to be the same species.

Contrasting the homogeneity in types of chromosomes for northwest Pacific species, the northeast Pacific species evaluated so far indicate less homology in the numbers of metacentric (m), submetacentric (sm), and subtelocentric (st) chromosomes between species (*H. cracherodii* with 8 m: 8 sm: 2 st, but *H. fulgens* with 10 m: 3 m-sm: 4 sm: 1 sm-st, and *H. rufescens* with 8 m: 6 m-sm: 3 sm: 1 sm-st. Lack of homology in karyotypes has also been reported for the Indo-Pacific species studied so far, which are characterized by a diploid chromosome number of $2n = 32$. However, lack of homology in karyotypes has been reported also for what is now believed (Lee & Vacquier 1995) to be the same species (Table 2). This result can be explained by the reduced sample size used for karyotyping, or by using low quality metaphases. For example, within this group of Indo-Pacific abalone species, two conflicting karyotypes have been reported within

Figure 3. Karyo-idiogram of *H. fulgens* and *H. rufescens*. Relative lengths and confidence intervals of each species chromosome short and long arms are plotted: *Haliotis fulgens*, squares; *Haliotis rufescens*, circles. Chromosome classification, m = metacentric, sm = submetacentric, st = subtelocentric.

(S) indicates within the same block species which have been later found to be the same one.

two species, *H. varia* (Nakamura 1986, Arai et al. 1988, Jarayabhand et al. 1998) and *H. diversicolor* (Nakamura 1985, Arai et al. 1988). Nakamura (1986) states that his data for *H. varia* are not precise because of the small size (1.41 to 3.63 μm) of some of the chromosomes he found, and Jarayabhand et al. (1998) attributes the difference in his study with that in Arai et al. (1988) to different methodological conditions. However, the microphotographs of *H. varia* karyotype included in Jarayabhand et al. (1998) indicate a possible problem with measurements because of the small chromosome size and a low definition of metaphases. The differences reported for karyotypes within *H. diversicolor* can be explained by one author classifying 2 chromosomes as submetacentric, whereas the other one classifies those chromosomes as submetacentric-subtelocentric, indicating that the centromeric index is in the limits of both classes, pointing again to the need for more detailed classification when the chromosome centromeric indices are in, or close to the limits of two classifications.

Based on the results obtained in this study, indicating that whereas the chromosomes of *H. rufescens* and *H. fulgens* do not differ in their relative length (RL), that 5 of the 18 chromosomes were different in centromeric index (CI), relative length of short arm, and relative length of long arm, it is possible to propose causes for the differences in chromosome structure between these two species. For all of those chromosomes that were different (4,

7, 9, 11, and 18), pericentric inversions can be proposed to be the evolutionary force differentiating the two species. Pericentric inversions represent a structural chromosome change known to be the most frequent mutations in the evolution of karyotypes (White 1978). Finally, another important difference between the karyotypes of the two species is the position of the only submetacentric-subtelocentric chromosome in each, based on decreasing RLs, which is in position on chromosome number 14 for *H. fulgens* and position on chromosome number 18 for *H. rufescens*, suggests a possible translocation event in the common lineage of these species.

A characteristic among abalone species reported in the literature is the presumable existence of hybrids. The occurrence of hybridization has been inferred from morphologic characteristics in natural populations (Owen et al. 1971) or from mating experiments in the laboratory (Leighton & Lewis 1982, Koike et al. 1988, Hoshikawa et al. 1998). However, genetic confirmation of hybridization has only been done for hybrids of *H. kamtschaticana* and *H. discus hannai* (Hoshikawa et al. 1998). Given the karyotype differences observed in this study it is possible to conclude that even if fertilization between these two species can be achieved producing hybrids, those hybrids would be expected to have a reduced fertility because of improper synapses of not perfectly homologous chromosomes during meiosis (Freeman & Herron 2001). In agreement, Leighton & Lewis (1982) found a low vi-

ability (0.1%) to postlarva when mating (presumed, not genetically certified) hybrids of red and green abalone.

ACKNOWLEDGMENTS

The authors thank the abalone laboratories BC Abalone, Erendira and Cooperativa de Buzos y Pescadores Isla, Nativi-

dad for the donation of biological material, and also Susana Avila from CIBNOR for laboratory technical support. The authors also thank Dr. Nick Elliot (CSIRO) and anonymous reviewers for valuable comments on the manuscript. This research was supported by CONACYT grant 38860-B to A. M. Ibarra.

A COMPARATIVE EVALUATION OF THE HABITAT VALUE OF SHELLFISH AQUACULTURE GEAR, SUBMERGED AQUATIC VEGETATION AND A NON-VEGETATED SEABED

JOSEPH T. DEALTERIS, BRIAN D. KILPATRICK, AND ROBERT B. RHEAULT

Department of Fisheries and Aquaculture, University of Rhode Island, Kingston, RI 02881

ABSTRACT The habitat value of modified rack and bag, shellfish aquaculture gear (SAG) used for the grow-out phase of the American oyster, *Crassostrea virginica*, submerged aquatic vegetation (SAV), *Zostera marina*, and a shallow nonvegetated seabed (NVSb) was comparatively evaluated over a 1-year period in Pt. Judith Pond, a tidal estuary in Southern Rhode Island. Enclosure gear was used to sample the three ecotypes, and organisms (>5 mm) were identified, enumerated, and measured to the nearest millimeter. Abundances of marine organisms and species diversity indices were used as measures of the habitat value of these ecotypes within each season. Environmental and geological parameters were not significantly different between the habitats. Emergent surface area ($\text{cm}^2 \text{m}^{-2}$ of seabed) within each ecotype was estimated, and used to evaluate its role in providing habitat. The SAG habitat had a significantly greater surface area than either the SAV or NVSB habitats during all seasons. The physical structure of the SAG habitat protects juvenile fish from predators and provides substrate for sessile invertebrates that serve as forage for fish and invertebrates. The SAG habitat supported a significantly higher abundance of organisms per m^2 of seabed throughout the year. Species richness was also significantly greater in the SAG habitat compared with the SAV and NVSB habitats. A 2-way ANOVA indicated significant differences in species diversity (Shannon-Weiner index) between habitats. Tukey's HSD test indicated that the SAG habitat had significantly higher species diversity than the NVSB habitat, but no significant difference in species diversity was found between the SAG and SAV habitats. These findings indicate that shellfish aquaculture gear provides habitat for many organisms throughout the year, and is especially beneficial to ecosystems that support native species of recreationally and commercially important fish and invertebrates in their early life history stages. Therefore, we conclude that shellfish aquaculture gear has substantially greater habitat value than a shallow nonvegetated seabed, and has habitat value at least equal to and possibly superior to submerged aquatic vegetation.

KEY WORDS: shellfish aquaculture, habitat value, submerged aquatic vegetation

INTRODUCTION

Habitat is the place where an organism lives (Odum 1971). This simple definition is the basis for most ecologic studies involving habitat quality or value. Other considerations regarding the definition of habitat are that an organism at any particular life stage has only one habitat and that an organism's spatial distribution defines its habitat (Minello 1999). The characteristics of habitat that have been identified as being beneficial to organisms include physical structure, provision of food, substrate, hydrodynamics, and hydrology, and these must be specified to quantify habitat utilization by a particular species (Minello 1999). Physical structure is provided by submerged aquatic vegetation (SAV) or man-made structures like artificial reefs. The terms habitat "value" or "quality" when pertaining to fishery resources is defined as a habitat's ability to support a fishery resource (finfish, crustaceans, molluscs, and all other forms of marine animal and plant life). Studies that describe fishery resource habitat value primarily use species density or abundance data (Able, 1999). The purpose of this study is to comparatively evaluate the habitat value of modified rack and bag, shellfish aquaculture gear (SAG) used for the grow-out phase (Rheault & Rice 1995) of the American oyster, *Crassostrea virginica*, submerged aquatic vegetation (SAV), *Zostera marina*, and a shallow nonvegetated seabed (NVSb) over a 1-year period in Pt. Judith Pond, a tidal estuary in southern Rhode Island. The SAG habitat uniquely supplies an abundance of substrate due to the wire racks and rigid, plastic bags, in addition to the shell of the cultivated oyster.

In a study designed to estimate relative habitat value, Smith et al. (1989) used mark-recapture data and estimated densities of scallops (*Argopectin irradians*) to compare a recently transplanted eelgrass (*Zostera marina*) bed to a natural eelgrass bed. In a similar study, Fonseca et al. (1996) used abundances of shrimp, fish, and crab species to assess habitat value of the replanted eelgrass as compared with nonvegetated areas and naturally occurring eel-

grass meadows. Recent studies involving oyster reefs have used similar criteria to determine relative habitat value by sampling nekton densities within the reefs. Coen et al. (1999a) conducted a long-term study comparing the habitat value of oyster reefs in the southeastern United States by measuring several parameters, including water quality and abundances, of resident and transient fauna. Faunal densities were used to compare species richness between natural and experimental reefs. Carr and Hixon (1997) compared fish assemblages and abundances to determine species richness on natural and artificial reefs. O'Beirn et al. (2001) investigated the organisms associated with oysters cultured in floating systems by measuring the number of macro-faunal species inhabiting these floating culture systems, so as to determine the species richness of this unique habitat.

Natural oyster reefs have been identified as essential fish habitat because not only do they support the oysters themselves but a myriad of other fishery resources. There is abundant evidence that indicates these reef communities are extremely diverse and show differences in species abundances as compared with adjacent non-vegetated, sand flat habitats. Oyster reef habitats are not only highly diverse but include species absent in adjacent soft-bottom environments (Coen et al. 1999b). In addition to obligate oyster reef residents, a variety of transient species occupy the reef in a facultative way (Posey et al. 1999). Grass shrimp, blue crabs, and other fish were observed utilizing the reefs possibly for foraging or refuge purposes. Breitburg and Miller (1998) reported that resident finfish populations are dependent on oyster reef habitats due to the physical extent of the reefs, their suitability as refuges from predators, and abundance of prey for consumption. These characteristics influence the abundance, growth, and reproduction of these resident finfish, thus demonstrating that oyster reefs enhance fish production. There is evidence that the 3-dimensional structure of oyster reefs affect the spatial distribution of various fish and perhaps the overall abundances. Striped bass and other predatory fish have

been observed to hover near reefs utilizing them as foraging sites (Breitburg 1999).

Habitats that exhibit structural complexity have been shown to support higher numbers of species as compared with barren non-vegetated bottom types (Orth & Heck 1980). Orth et al. (1984) concluded that an increase in habitat complexity due to eelgrass density should increase refuges for prey species. Man-made structures have also been shown to increase abundances of fishery resources (Carr & Hixon 1997). Man-made structures or "artificial reefs" may be specially constructed and consist of concrete rubble (Kelch et al. 1999) used for the purposes of creating habitat for fish. Grossman et al. (1997) hypothesized that if habitat is limiting, new artificial reefs can potentially increase fish production through 3 mechanisms: (1) an increase of foraging habitat for adult, juvenile, and/or newly recruited fishes; (2) an increase in breeding habitat; and (3) an increase in predator refuge or resting habitat. Therefore, shellfish aquaculture gear may serve as an artificial reef habitat by virtue of its inherent structural complexity and extensive time spent on the seafloor throughout the year, thereby increasing the fish production in the ecosystem.

MATERIALS AND METHODS

Study Area

Three habitats (SAG, SAV, and NVSB) were sampled in Pt. Judith Pond, Rhode Island, a shallow 6 km tidal estuary that discharges into Block Island Sound. The 1.0 h aquaculture lease site contained over 600 oyster cages, each consisting of a 1.8 m \times 0.6 m \times 0.6 m wire cage that held 12 mesh bags of shellfish on shelves. The oyster cages were placed 2.4–6.1 m apart on the seabed in 2.4–3.0 m of water. The SAV and NVSB habitats were located approximately 1.5 km south of the aquaculture lease in Pt. Judith Pond at similar depths of water.

Experimental Design

The research design was a four (season) by three (habitat type) factorial design with three replicates within each habitat. Three habitats (SAG, SAV, and NVSB) were seasonally sampled in replicate between December 2000 and October 2001 so as to evaluate the following habitat characteristics: macro-epibenthic fauna community structure, and the physical, chemical, and geological environmental conditions. All three habitats sampled using enclosure type gears to maximize the efficiency and consistency of sampling (Rozas & Minello 1997).

Field and Laboratory Methods

Moonstone Oyster Company cultivates the American Oyster (*Crassostrea virginica*) in cages that are cleaned every 4–6 months. We selected cages for sampling that had been cleaned 4–6 weeks prior to each seasonal sampling so that they would have a representative seasonal fouling population. Lift-nets (2.1 m \times 0.9 m with a 2-mm mesh) were placed beneath three randomly selected SAG units 2 weeks before sampling to allow sufficient time for swimming organisms to return to the cages following the disturbance of lifting the cage to place the lift nets underneath.

A scuba diver deployed the lift-net so that it completely enclosed the oyster cage during recovery. All free swimming epifauna >5 mm were recovered from the lift net enclosure along with three randomly selected oyster bags, and were taken back to the laboratory for analysis. Each oyster cage was also randomly

sampled in five locations with a 0.022 m² (15 cm \times 15 cm) quadrat to assess sessile invertebrate growth. The oyster cages are constructed of 5.1 cm mesh, vinyl-coated, 2 mm diameter wire. Percent cover of each biofouling organism within each quadrat sample was assessed to the nearest class and/or phylum. The percent cover of sessile invertebrate growth on the oyster bags was determined in a similar fashion. Total biomass of sessile invertebrates on the cages and bags was estimated for the entire surface area of the cages and bags by extrapolating mean sample values to the total surface area. A random subsample of 10 oysters was taken from each of three bags taken from each cage. Oyster length and width was measured to the nearest millimeter using vernier calipers and the surface area of the oysters and sessile invertebrate growth on both sides was estimated to the nearest square centimeter. Results were averaged within seasons and extrapolated over an average of 200 oysters per bag or 2,400 oysters per cage. The total surface area and sessile invertebrate coverage (cm²) for each oyster cage consisted of the sum of the surface area of the oyster cage, the 12 oyster bags, and the seasonal average surface area of the 2,400 oysters. These sums were divided by the area enclosed by the lift net used to sample the SAG habitat (1.95 m²). Thus, surface area and invertebrate growth are referenced to area (m²) of the seabed.

The SAV and NVSB habitats were sampled on the same day within a few hours of noontime during each of the seasons. These habitats were randomly sampled using a 2-mm mesh drop-net (2.13 m \times 0.92 m) and a venturi-driven suction dredge deployed from a small skiff. The animals were collected in a 2 mm-mesh catch bag and returned to the laboratory for analysis. The emergent portion of the SAV habitat was randomly subsampled with a 0.25 m² quadrat (3 replicates) each season. The eelgrass blades within each quadrat were clipped at the base and measured to the nearest 100 cm using vernier calipers. Sessile invertebrate growth (cm²) on the SAV was similarly estimated. The NVSB habitat was devoid of emergent substrate and attached sessile invertebrates.

All free swimming organisms >5 mm in length collected from each of the three habitats were identified to the genus and species, and measured to the nearest millimeter using vernier calipers. Temperature, salinity, and dissolved oxygen were seasonally measured during each sampling event in each habitat. Sediment from each habitat was collected seasonally using a 7.5-cm diameter \times 15.2-cm deep corer. Mean sediment grain size was determined by dry sieve analysis (Folk 1968).

Data Analysis

Seasonal environmental parameters (temperature, salinity, and dissolved oxygen) were analyzed by 2-way analysis of variance (ANOVA) without replication (EXCEL 1997) between habitat and season. The environmental dependent variables for each season were also analyzed using 1-way analysis of variance (ANOVA). Tukey's honest significant difference (HSD) test was used to compare treatment means when an F-test indicated significant treatment effects (SPSS vs.10 1999). Sediment type data for each habitat was characterized according to percent gravel, sand, and silt-clay using a 2-way ANOVA without replication (EXCEL 1997) between habitat and season. This analysis was repeated after subtracting the gravel component from the oyster cage habitat to compensate for the presence of shell hash from the aquaculture operations. Physical habitat complexity was measured in terms of emergent surface area within each habitat. The average surface area within each of the replicates for each habitat was log transformed

($\ln(\text{cm}^2)$) to satisfy the homogeneity of variance assumption for an analysis of variance (Zar 1984). The average surface area was compared with a 2-way ANOVA (SPSS vs.10 1999) between habitats and seasons, and Tukey's HSD test (SPSS vs.10 1999) was used to compare treatment means when an F-test indicated significant treatment effects.

The community structure was analyzed using Ecological Methodology (Krebs 1989) statistical software (Exeter Software 2000). The raw data used in the statistical software consisted of species abundances (3 replicates) within each habitat for each season. Species richness was determined by the Jackknife method for quadrat counts (Heltsh & Forrester 1983). Shannon-Weiner species diversity and Smith and Wilson species evenness indices were generated using Ecological Methodology statistical software (Exeter Software 2000). The indices of species richness, diversity, and evenness within each habitat were each analyzed using a 2-way ANOVA (SPSS vs.10 1999) between habitat and season. Tukey's HSD test (SPSS vs.10 1999) was used to compare treatment means when an F-test indicated significant treatment effects.

Species abundance data within each habitat were compiled into 5 categories for analysis: total abundances of all organisms sampled, fish, crustacean, mollusk abundances, and total surface covered by sessile invertebrates. The abundance data were log transformed ($\ln(X)$) to satisfy the homogeneity of variances assumption (Zar 1984) and analyzed using a 2-way ANOVAs (SPSS vs.10 1999) between habitat and season for each abundance category. Tukey's HSD test (SPSS vs.10 1999) was used to compare treatment means when an F-test indicated significant treatment effects. Correlation analysis (EXCEL 1997) was used to investigate the relationship between the total abundance of animals observed in each habitat and season, and the emergent surface area found in each habitat and season.

RESULTS

Environmental Parameters and Sediment Characteristics

There were no significant differences in temperature, dissolved oxygen, or salinity between sites ($P < 0.05$) in any given season. Temperature varied seasonally from 3.0 to 23.7 °C; salinity was influenced by rainfall and ranged from 25.0 ppt to 34.6 ppt; and dissolved oxygen peaked in winter/spring at 11.9 mg/L and was lowest in spring/summer at 6.4 mg/L. The three sampling sites had a similar grain size composition, dominated by sand (mean 93.5%) and silt-clay (mean 6.5%), however there was a substantial gravel component (4.27%) in the SAG site that was comprised primarily of oyster shell fragments. After removing this fraction, the sediments from the three sites were not significantly different from each other ($P < 0.05$).

Habitat Structure

Habitat structure, described in terms of emergent surface area (cm^2) per m^2 of seabed, varied as a function of habitat type and season (Fig. 1). The log transformed average emergent surface area varied significantly both between sites and between seasons ($P < 0.001$). There were significant differences ($P < 0.05$) between each of the 3 habitats (SAG>SAV>NVSB), and significant differences ($P < 0.01$) between each of the seasons (except between spring/summer and winter/spring). The SAG habitat, due to the cages, bags, and oysters, provided an average of more than 60 times the emergent surface area per square meter over the course

Figure 1. Emergent surface area (cm^2/m^2 of seabed) for each habitat and season.

of the year than the SAV habitat. The SAV habitat had mean shoot densities of 554/ m^2 in the spring/summer and summer/fall seasons and 224/ m^2 in the fall/winter and winter/spring seasons. The NVSB habitat was devoid of emergent surface area during all seasons.

Community Structure

Species richness was also consistently higher in the SAG habitat (Fig. 2a). There were significant differences ($P < 0.01$) between habitats, and between seasons ($P < 0.05$). Species richness was significantly different between each habitat (SAG>SAV>NVSB) and between fall/winter and summer/fall seasons. The mean Shannon-Weiner Index values of species diversity were highly significantly different between habitats ($P < 0.001$) and between

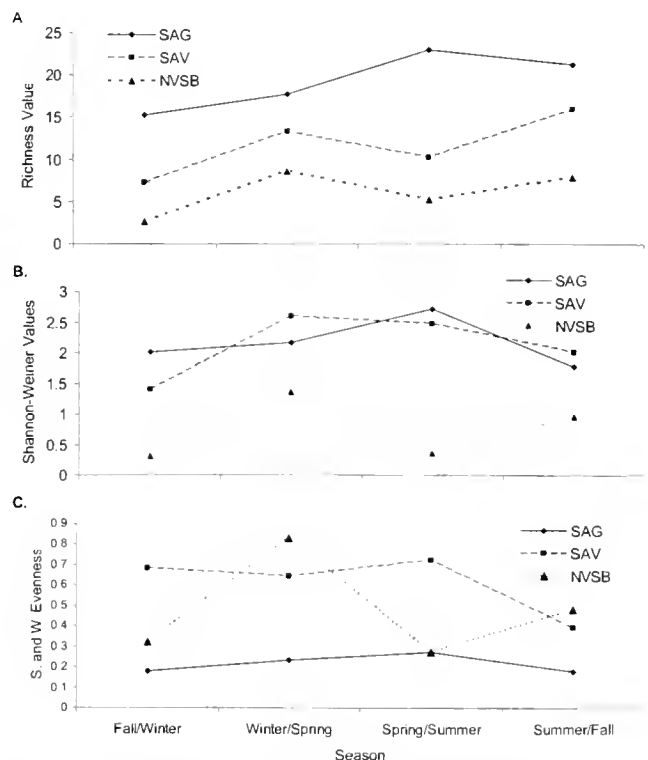

Figure 2. A. Species richness values for each habitat and season. B. Mean Shannon-Weiner values for each habitat and season. C. Mean Smith and Wilson measure of evenness values for each habitat and season.

seasons ($P < 0.01$). The SAG habitat was not significantly different from the SAV habitat ($P > 0.05$), however both of these habitats were highly significantly different ($P < 0.01$) from the NVSB (see Fig. 2b). Significant differences ($P < 0.05$) in species diversity were also found between the fall/winter and winter/spring sampling and between fall/winter and spring/summer. The SAG habitat showed consistently lower Smith and Wilson species evenness values than either the SAV or NVSB because a few species tended to dominate this habitat (see Fig. 2c). There were highly significant differences in species evenness between habitats ($P < 0.001$), but not between seasons ($P > 0.05$). The SAG habitat was significantly lower in species evenness than either the SAV or NVSB habitats ($P < 0.05$).

Species Abundances

The SAG habitat consistently supported far greater abundances of organisms than either the SAV or the NVSB habitats throughout the year (Fig. 3). There were highly significant differences ($P < 0.001$) between habitat and seasons for the species abundance data. There was a highly significant difference ($P < 0.001$) in species abundance between each habitat (SAG>SAV>NVSB). There was also a significant difference ($P < 0.05$) in species abundances between all seasons except winter/spring and spring/summer sampling periods showed no significant differences ($P > 0.05$). A strong correlation ($r = 0.94$) was found between the total abundance of organisms in each habitat and season and the emergent surface area available in corresponding habitat and season (Fig. 4).

Ten fish species were identified inhabiting one or more of the three habitats sampled during the course of the study (Fig. 5), and individual fish species abundances are shown for each habitat and season in Figure 6. There were highly significant differences ($P < 0.001$) in fish abundances between habitats and seasons. The greatest fish abundances ($P < 0.01$) occurred in the SAG habitat followed by the SAV habitat and then the NVSB habitat. The summer/fall sampling period had significantly higher ($P < 0.01$) fish abundances compared with any other season. With two exceptions, the SAG habitat supported higher abundances of fish than either SAV or NVSB habitats. The Northern Pipefish (*Syngnathus fuscus*) in the spring/summer and summer/fall and the Winter Flounder (*Pleuronectes americanus*) in the summer/fall were unique to the SAV. There were many species of fish that were unique to SAG including the American eel (*Anguilla rostrata*), oyster toadfish (*Opsanus tau*), rock gunnel (*Pholis gunnellus*), and Atlantic tomcod (*Microgadus tomcod*). Several fish species were sampled throughout each season in the SAG, which included the seaboard

Figure 3. Total abundances of organisms collected within each habitat and season.

Figure 4. Correlation of total abundance of organisms (abundance) and emergent surface area (surface area cm²/m² of seabed).

goby (*Gobiosoma ginsburgi*), grubby (*Myoxocephalus aeneus*), tautog (*Tautoga onitis*), and cunner (*Tautogalabrus adspersus*). The SAG habitat was the only habitat sampled that supported one or more fish species year-round.

Thirteen crustacean species were identified to inhabit one or more of the three habitats sampled during the course of the study (Fig. 7), and individual crustacean species abundances are shown for each habitat and season in Figure 8. There were highly significant differences ($P < 0.01$) in crustacean abundances between habitats and seasons. The greatest abundances occurred in the SAG habitat followed by the SAV habitat and then the NVSB habitat. The summer/fall sampling period had significantly higher ($P < 0.01$) crustacean abundances compared with any other season. The American Lobster, *Homarus americanus*, was the only crustacean unique to the SAG habitat (5 observed individuals). The average carapace length was 6.3 cm (S.E. \pm 0.88), which places these lobsters in the juvenile phase of their lifecycle (Hudon 1987).

Seven mollusk species were identified to inhabit one or more of the three habitats sampled during the course of the study (Fig. 9), and individual mollusk species abundances are shown for each habitat and season in Figure 10. There were highly significant differences ($P < 0.01$) in mollusk abundances between habitats and seasons. The greatest abundances occurred in the SAG habitat followed by the SAV habitat and then the NVSB habitats. The winter/spring sampling period had significantly higher ($P < 0.01$) crustacean abundances compared with any other season.

Sessile invertebrate species were present in both SAG and SAV habitats (Fig. 11). The NVSB habitat was devoid of surface and hence the absence of sessile invertebrates. Statistics were not performed to detect differences between habitats due to the high variability of sessile invertebrate abundances.

Figure 5. Total fish abundances found within each habitat and season.

Total abundances (Ln(abundance+1)) of individual fish species found within each habitat during: A. fall/winter, B. winter/spring, C. spring-summer, and D. summer-fall sampling periods for the following species: *Anguilla rostrata*, *Gobiosoma* spp., *Microgadus tomcod*, *Myoxocephalus aeneus*, *Opsanus tau*, *Pholis gunnellus*, *Pleuronectes americanus*, *Syngnathus fuscus*, *Tautoga onitis*, *Tautoglabrus adspersus*.

DISCUSSION

Habitat is the place where an organism lives during any part of its lifecycle (Odum 1971). The ecologic value of habitat is inferred by quantifying the resident and transient marine organisms associated with a particular habitat. Consequently, the greater the abun-

Total abundances (Ln(abundance+1)) of individual crustacean species found within each habitat during: A. fall/winter, B. winter/spring, C. spring-summer, and D. summer-fall sampling periods for the following species: *Callinectes sapidus*, *Carcinus maenas*, *Crangon septemspinosa*, *Gammarus* spp., *Hemigrapsus sanguineus*, *Hippolyte* spp., *Homarus americanus*, *Libinia emarginata*, *Dyspanopeus sayi*, *Pagurus longicarpus*, *Panopeus* spp., *Upogebia affinis*.

dance and diversity of fish in a particular habitat, the greater its habitat value (Able 1999). SAV and natural oyster reefs have been identified as important fish habitats not only because of shelter they provide to resident and transient marine organisms, but also because of the ecologic services they provide to the surrounding environment. The objective of our study is to comparatively evaluate the habitat value of SAG, SAV and NVSB in a small estuary. The SAV habitat sampled in this study is typical of other SAV

habitats in New England and the mid-Atlantic regions based on eelgrass shoot density (Thayer et al. 1984).

The environmental parameters were relatively consistent among habitats within each season. No significant differences were observed between habitats for temperature, salinity, and dissolved oxygen, as was expected considering each habitat is contained within the same estuary. Also, as expected, the major differences among environmental parameters occurred between seasons. Sediment type between habitats was found to be similar after

Figure 11. the gravel component was removed from the SAG site. The gravel component in the SAG site consisted of shell hash, which is a direct result of the aquaculture activities that take place over the seabed. The differences observed in species abundances and diversity between habitats are not likely to be related to environmental or geological parameters. Therefore, we believe that the observed differences in species composition and abundances are influenced by differences in habitat composition, structure, and complexity.

There was a highly significant difference in emergent surface

area (cm^2) between each habitat that was strongly correlated with abundance of organisms observed. The NVSB habitat supported significantly fewer organisms than either SAV or the SAG habitats throughout the year. The SAV emergent surface varied throughout the year due to seasonal growth and mortality patterns. The SAG emergent surface area varied seasonally as a result of the measured changes in the surface area of the oysters, whereas the surface area of the cages and bags remained constant. We believe that the higher abundances of species found in the SAG habitat throughout the year are related to the high surface area, the large numbers of spaces inside the cages that serve as refuge, and the prevalence of fouling organisms and forage. Structural heterogeneity was not considered when quantifying each habitat. The SAG habitat is constructed of 2-inch (5.08 cm) plastic-coated wire mesh. It can be assumed that the size of the wire mesh restricted many of the predator species of certain sizes and hence the cages became a refuge for many of the juvenile species of fish. These results are consistent with many studies that have recognized increased habitat complexity supports higher abundances of organisms due to increased predator protection (Orth et al. 1984, Ryer 1988, Beck 2000).

The high surface area within the shellfish aquaculture gear provides habitat not only for mobile fauna but also sessile biofouling invertebrates. Sponges, hydroids, bryozoans, and ascidians were found in both the SAG and SAV but the SAG habitat clearly displayed larger abundances of sessile invertebrate species. The SAV does support epiphytic and sessile invertebrate growth but not to the extent of the SAG. Although not intensively studied in this research, sessile invertebrate communities form the base of the food web for many artificial reef communities (Blancher et al. 1994). The high prevalence of sessile invertebrate communities on the SAG not only increases habitat complexity, but also increases food resources for the marine organisms inhabiting the aquaculture gear.

The SAG habitat shares many attributes and similarities with natural oyster reefs and artificial reefs. The oysters within the aquaculture gear are providing many of the same ecologic services as those found within naturally occurring oyster reefs. These ecologic services include but are not limited to particle clearance, nutrient removal and remineralization, benthic-pelagic coupling, and the creation of refuge from predators (Coen et al. 1999a, Dame 1999). The SAG also provides 3-dimensional structural complexity and many of the same benefits that artificial reefs provide in areas where habitat is limiting. Studies have shown and suggested that biologic services of artificial reefs include foraging habitat and predator refugia to resident and transient marine organisms (Blancher et al. 1994, Bohnsack 1989).

The abundance (organisms $>5\text{mm}$) and species richness exhibited in the aquaculture gear was greater than the eelgrass habitat, which in turn was greater than the unvegetated site, consistent with previous studies (Orth & Heck 1980, Mattila et al. 1999, Heck et al. 1995). This research clearly indicates more organisms inhabit the SAG habitat either SAV or NVSB habitats per square meter of seabed throughout the year. Species diversity levels were similarly higher in the shellfish aquaculture gear and the eelgrass ecotypes than in the unvegetated bottom consistent with findings of Marshall-Adams (1976), Mattila et al. (1999), Heise & Bortone (1999). Average species diversity in the SAG habitat was higher, but not significantly, than in the SAV habitat. The evenness measures

varied greatly for each habitat throughout the year, however the SAG habitat had consistently lower evenness than the other ecotypes because of the hyperdominance of several species within the aquaculture gear (*Dyspanopeus sayi*, *Tautogalabrus adspersus*, and *Mytilus edulis*). In contrast, the SAV habitat was rarely dominated by a few species, but rather supported a more equal distribution of organisms. The NVSB habitat showed a greater fluctuation of evenness values directly affected by the abundances of the sand shrimp (*Crangon septemspinosa*) sampled during each season. The sand shrimp was by far the most dominant species in the NVSB habitat and accounted for 87% of the NVSB organisms sampled throughout the year.

The abundance and species diversity data elucidate the similarities and differences between each of the three habitats. The oyster cages supported much greater species abundances than eelgrass, but displayed similar species diversity (as shown by the Shannon-Weiner index). Eelgrass is a habitat known to provide many valuable ecosystem services and has been demonstrated to be a critical and essential habitat to many commercial and recreationally important species. The species abundance and diversity data from this study suggest that the shellfish aquaculture gear has similar habitat value for its inhabitants when compared with eelgrass. The species evenness data clearly shows that whereas the abundances may be greater in the SAG habitat, the SAG habitat is dominated by a few species.

The SAG habitat may also act as a predator refuge during early life stages of the lobster due to the limiting habitat within Point Judith Pond. In the spring and summer small lobsters are regularly found in the oyster cages and large predatory fish have been observed to frequent the aquaculture lease area including: the American shad (*Alosa sapidissima*), striped bass (*Morone saxatilis*), and winter flounder (*Pleuronectes americanus*). The American lobster supports an important fishery in the northeast United States therefore any habitat found to support the lobster should be considered commercially beneficial.

There is little research to date that describes the ecosystem services and benefits of aquaculture gear and its associated cultured product. The ecosystem services of the cultured bivalves and the benefits they provide to the marine ecosystem are fundamentally similar to those provided by wild stocks of bivalves. The aquaculture gear used to grow the cultured bivalves has intrinsic habitat complexity and shares many of the characteristics that artificial reefs possess. However, aquaculture gear is not a fixed structure, but it is periodically disturbed during maintenance and harvest operations. Most SAG habitat organisms are undoubtedly displaced during cleaning operations. Some of the sessile organisms are killed, but, the mobile species are probably able to quickly relocate to another of the 600 cages nearby when they are disturbed. The maintenance and cleaning of the aquaculture gear initiates recolonization of sessile invertebrate growth and inhabitation by motile organisms.

These findings indicate that shellfish aquaculture gear provides habitat for many native species of recreationally and commercially important fish and invertebrates in their early life history stages throughout the year. Therefore, we conclude that shellfish aquaculture gear has habitat value at least equal to and possibly superior to submerged aquatic vegetation. Future research should focus on growth, survival, and production of fish biomass within this habitat to further elucidate its habitat value.

MOLLUSCAN COMMUNITIES OF THE ROCKY INTERTIDAL ZONE AT TWO SITES WITH DIFFERENT WAVE ACTION ON ISLA LA ROQUETA, ACAPULCO, GUERRERO, MÉXICO

ARCADIO VALDÉS-GONZÁLEZ,^{1,*} PEDRO FLORES-RODRÍGUEZ,^{1,2}
RAFAEL FLORES-GARZA^{1,2} AND SERGIO GARCÍA-IBÁÑEZ¹

¹Doctorado en Ciencias Biológicas, Especialidad en Ecología, Facultad de Ciencias Biológicas, Universidad Autónoma de Nuevo León, San Nicolás de los Garza, Nuevo León, México. C. P. 66450;

²Universidad Autónoma de Guerrero, Unidad Académica de Ecología Marina, Acapulco, Guerrero, México. C. P. 39390

ABSTRACT Molluscan communities were studied on two shores, one exposed and the other sheltered from wave action by determining the diversity, richness, density, dominance, and similarity of the groups of species found in the upper part of middle intertidal zone. The sample area per location and date was 20 m². The samples were taken quarterly during the year. Species richness was found to be 44 species for both sites combined. The exposed site had a greater richness (41 species) and lower density (64.2 organisms/m²), whereas the sheltered site showed a higher density (88.08 organisms/m²) and smaller richness (33 species). Thirty species (68.8%) were determined to be common. The exposed shore had more confined species. The Shannon-Wiener diversity index (*H'*) was higher for the exposed site (3.165 bits/individual). A comparison of means by the Mann-Whitney tested indicated that the annual means of *H'* were equal between the two sites. Qualitative (Jaccard) and quantitative (Morisita-Horn) similarity scores were high at 0.682 and 0.622, respectively. The mean density of gastropods was the same at both locations, because bivalves showed significant differences with higher densities at the sheltered site. The malacologic community of the two sites was very similar. However, changes in richness and diversity over time were greater at the sheltered shore, while these changes were more gradual at the exposed shore, reflecting a greater stability of the malacologic community at the latter location.

KEY WORDS: molluscan communities, rocky intertidal, wave action, Acapulco

INTRODUCTION

The Pacific rocky coast has a very variable relief, which determines microenvironmental conditions at each location, which in turn control the distribution of species. Molluscs stand out because of their abundance and variety of forms, and have been connected with the development of many cultures.

It is important to measure some of the ecological attributes of the communities, so that comparison can be made with species found at other locations. The information also has practical application for the purpose of management, appropriate use, conservation, and environmental monitoring. On the overall geographic scale, climate is the principal factor that determines the type of communities, whereas on a smaller scale it is more difficult to establish which factors govern the grouping of species. Various physical factors are known to intervene in the shaping of the structure of communities, one of them being exposure to waves. Studies of molluscan populations and communities along the Mexican Pacific have historically focused on species of commercial interest (Baqueiro & Stuardo 1977, Baqueiro 1979, Ríos-Jara et al. 2001), and the majority of these have been conducted on the continental shelf (Reguero & García-Cubas 1989, Landa-Jaime & Arciniegas-Flores 1998). There have been few investigations in the particular case of rocky shores, where most of the authors have carried out taxonomic works (Morris 1966, Keen 1971, Holguín-Quiñones & González-Pedraza 1989, 1994, Sevilla 1995, Reyes-Gómez & Salcedo-Vargas 2002), and others have been concerned with the zonation, richness and species diversity of molluscs (Villalpando-Canchola 1986, Salcedo-Martínez et al. 1988, Castillo-Rodríguez & Amezcua-Linares 1992, Román-Contreras et al. 1991, Esqueda et al. 2000, Villarreal et al. 2000) and the different regions exposed

to waves (García-Lopez 1994, Del Río-Zaragoza & Villarreal-Melo 2001).

The main economic activity in the State of Guerrero is tourism and to a lesser degree fishing. However, there is little known about marine faunistic resources, despite that it involves an extensive coastline that encompasses three marine regions prioritized for the conservation of the coastal and ocean biodiversity of Mexico, and Mexico's National Commission on Biodiversity (CONABIO) has indicated that there is a lack of knowledge about this region (Arriaga et al. 1998). Isla La Roqueta is located within this zone.

The aim of this investigation is to determine the diversity, density, dominance, and similarity among the groups of mollusc species in the high intertidal zone of a shore exposed to wave action and one not, under the supposition that locations that differ in exposure also differ in composition of the malacologic community.

METHODS

Area of Study

Isla La Roqueta is located in Acapulco, Guerrero, and the sample sites were as follows: (a) Playa Zoológico is situated 16°42'11.2"N and 99°54'8.8"W, and is a shore exposed to wave action. Its massif is composed of intrusive igneous rocks, and has a firm substrate with a large amount of fissures, cracks, and cavities all over the area; (b) Playa Palmitas is situated 16°49'25.6"N and 99°54'41.2"W. It is a sheltered shore with a massif composed of intrusive igneous rocks. It has a firm substrate with a large amount of fissures, cracks, and cavities. The climate is hot and sub-humid, with rains in the summer and with 5% to 10% winter rain (García 1981).

Field Methods

The sample was taken from the upper part of middle intertidal zone of the two locations. The sampling dates were December of

*E-mail: acuacu_uanl@yahoo.com.mx

2000 and March, June, September and December of 2001. The calculated area for the sample size was 20 m² for each station, determined by the method of species area (Brower et al. 1998). Collection was at 2 vertical levels of the upper part of the middle intertidal zone, called level I with its lower limit adjacent to the barnacle zone, and level II with its upper limit next to the periwinkle and limpet zone. A strip 30 m long and 2 m wide was used, which was parallel to the coastline, and the sampling unit was a quadrant 1 m squared. Sampling was systematic (Scheaffer et al. 1987), randomly selecting the starting point and placing the quadrant in level I. After finishing the first sampling unit, the quadrant was placed in level II, directly above level I. All the molluscs that were found in the quadrant were identified and counted. After completing both levels, a space of 2 m was left before establishing new quadrants until completing 20 m².

Taxonomic identification of the molluscs was according to Morris (1966), Keen (1971), Skoglund (1991, 1992), Reyes-Gómez and Salcedo-Vargas (2002).

Analysis of Data

The density of the molluscs was determined as number of organisms/m². Species richness constituted the number of species present per site. A species was considered dominant if it showed a density equal to or greater than 1 organism/m² in at least one of the samplings. Cumulative dominance was defined as the sum of individual dominances. The frequency of appearance was deter-

mined as the total number of samples in which each species was recorded and expressed as a percentage. A confined species was defined as the only species present in one of the sites. The difference between means of species richness was evaluated with the Mann-Whitney test (Daniel 2002). Similarity between the sites was measured by using the qualitative presence/absence index of Jaccard and the quantitative Morisita-Horn index based on abundance (Magurran 1989). Species diversity was determined with the Shannon-Wiener index H' (Margalef 1974), and the Mann-Whitney test was used to compare the mean values of diversity H' (Daniel, 2002).

RESULTS

Exposed Shore

A total of 41 species were found (Table 1) corresponding to 31 genera and 19 families, of which 75.6% belonged to the class Gastropoda, 17.1% to the class Bivalvia, and 7.3% to the class Polyplacophora. The lowest richness was found in the samplings of March and June with 21 species and the greatest in December of 2001 with 26 species (Fig. 1).

The mean density during the annual cycle was 64.2 organisms/m², which fluctuated among the different sampling times from 29.9 to 87.3 organisms/m².

Sixteen dominant species were recorded and in the annual cycle these species accumulated to 98.02% dominance. The quantity of

^CCommon species in both sites, ^FConfined species in exposed site, ^SConfined species in sheltered site.

Figure 1. Species richness observed by sampling dates for the exposed and sheltered sites on Isla La Roqueta, December 2000 to December 2001.

dominant species fluctuated per date from 5 in December of 2000 to 10 in December of 2001 (Table 2). The frequency of appearance of the dominant species was distributed in the following manner: nine had 100%, three 80%, three 60% and one 40%.

Of the 9 species that showed 100% frequency of appearance, the gastropod *Plicopurpura patula pansa* (Gould 1853) and the bivalve *Chama echinata* (Broderip 1835) had densities equal to or greater than 1 for all the sampling dates.

The densities of the class Gastropoda for all the dates were higher than those of the classes Bivalvia and Polyplacophora. The highest density of the class Gastropoda was seen in September of 2001, whereas the lowest was recorded in December of 2000. The

class Bivalvia showed the highest density in June and the lowest in September (Table 2).

The Shannon-Wiener index for the annual cycle was 3.165 bits/individual, oscillating among the different samples from 2.432 to 3.250 bits/individual (Fig. 2).

Sheltered Shore

A total of 33 species (Table 1) were found corresponding to 28 genera and 20 families, of which 78.8% belonged to the class Gastropoda, 18.2% to the class Bivalvia and 3.0% to the class Polyplacophora. The least richness was found in the samples of September with 16 species and greatest in December of 2000 and March and June of 2001 with 22 species (Fig. 1).

The mean density during the annual cycle was 88.08 organisms/m², which varied among the different sampling dates from 62.85 to 123.85 organisms/m².

Eleven dominant species were recorded and these species accumulated over the annual cycle to 98.26% dominance. The quantity of dominant species fluctuated per date from seven in December of 2001 to nine in June and September (Table 3). The frequency of appearance of the dominant species was distributed in the following manner: eight had 100%, two 80% and one 40% frequency. Of the 8 that showed 100% frequency of appearance, the gastropods *P. Panula pansa*, *Mancinella triangularis* (Bleainville 1832) and *Petalocochus complicatus* Dall, 1908 as well as the bivalves *Chama echinata*, *Brachidontes semilaevis* (Menke 1849) and *Isognomom janus* (Carpenter 1857) had densities equal to or greater than 1 at all the sampling dates.

The densities of the class Gastropoda were higher than those of the classes Bivalvia and Polyplacophora in the samples from June and September, whereas the class Bivalvia showed higher densities than those of the classes Gastropoda and Polyplacophora in samples from December of 2000 and March and December of

Figure 2. Shannon-Wiener diversity index values, observed for the exposed and sheltered sites on Isla La Roqueta, December 2000 to December 2001.

2001. The highest density for the class Gastropoda was seen in September of 2001, whereas the lowest was recorded in December of 2000. The class Bivalvia showed a higher density in December of 2001 and the lowest in September of the same year (Table 3).

The Shannon-Wiener index for the annual cycle was 2.863 bits/individual, oscillating among the different samples from 1.972 to 2.911 bits/individual (Fig. 2).

Both Sites

Thirty species (68.8%) were common to both sites. Eleven confined species were found at the exposed location, whereas there were only 3 at the sheltered site (Table 1). In the annual cycle, the Jaccard similarity index was 0.682 and the Morisita-Horn quantitative index was 0.622.

The mean number of species found per date was 23 species (SD = 2.12) for the exposed shore and 19.8 species (SD = 3.03) for the sheltered one. The difference between these mean values for

the two sites was not statistically significant (Mann-Whitney = 6.0, $P = 0.222$).

At the exposed site, the mean total density of dominant molluscs of the class Gastropoda for all the samples was 52.43 organisms/m² (SD = 21.24), whereas at the sheltered site it was 44.05 organisms/m² (SD = 33.03). A comparison of the two mean values showed no statistical difference (Mann-Whitney = 9.0, $P = 0.465$). For the class Bivalvia, there were 9.48 organisms/m² (SD = 7.13) at the exposed site and 42.5 organisms/m² (SD = 16.23) on the sheltered shore.

The two locations showed high diversity values, and in comparing the mean Shannon-Wiener indices for the five collections, there were no statistically significant differences (Mann-Whitney = 8.0, $P = 0.421$) (Fig. 2).

DISCUSSION

This study found a greater number species than that reported to date for the upper part of middle intertidal zone of the study area. Villalpando-Canchola (1986) collected 34 species at Isla la Roqueta, in an area referred to as level I, which included the upper part of middle intertidal zone, whereas García-López (1994) found 36 species in the same zone.

The exposed site showed a greater richness, more confined species, a higher number of dominant species, but a lower density. In all the samples, the class Gastropoda showed the greatest density. This site exhibited greater variation with respect to the number of dominant species among the sampling dates, and only two of these species had the characteristic of persisting during the entire cycle as dominant species. These findings indicate that the dominant community showed more mobility among its species.

The sheltered site showed less richness, fewer confined species, a lower number of dominant species, but a higher density. Among the samples, the highest densities per date alternated between the classes Gastropoda and Bivalvia. This location exhibited less variation with respect to number of dominant species among the sampling dates, and six of these species showed the characteristic of remaining the dominant species throughout the entire cycle. These findings indicate that the dominant community had less mobility among its species.

Total	37.15	48.15	38.55	22.3	66.35

Lewis (1964) found a greater richness and more confined species in an exposed site, and Del Río-Zaragoza and Villarroel-Melo (2001) also determined a greater number of species in an exposed site, whereas Spight (1978) reported a greater abundance in a sheltered site. However, García-Lopez (1994) reported a greater number of species at Isla la Roqueta for the sheltered sites studied.

The density of molluscs for the combined dominant species that belonged to the class Gastropoda did not differ between the two locations studied, and gastropods showed the highest abundance of species at both locations. Holguín-Quiñones and González-Pedraza (1989), Castillo-Rodríguez and Amezcua-Linares (1992), García-Lopez (1994), and Villarroel et al. (2000) also reported that gastropods displayed the greatest species richness among the classes of molluscs.

On the other hand, the density of molluscs for the combined dominant species belonging to the class Bivalvia did show differences between the two sites, such that the sheltered shore showed a greater number of bivalves.

The molluscs of the class Polyplacophora was recorded as dominant species only at the exposed location.

The percentage of cumulative dominance of the species that had densities equal to or greater than 1 organism/m² was similar for the two sites and was over 98% of the whole malacologic community.

A comparison of the mean values for species richness for all the sampling dates did not show significant differences, indicating that the two locations are similar with regard to richness. This same situation was seen when comparing the mean values for the diversity index H' , which indicates that the sites studied over the annual cycle can be considered equally diverse. However, the values recorded for both richness and the H' index of the sheltered site for each of the samples, demonstrated greater changes in the malacologic community, whereas in the exposed site these values showed more gradual changes.

In this study, the value for the Shannon-Wiener diversity measure for the exposed site was greater when considering the annual cycle. In a study of the same locations where the present work was conducted, García-Lopez (1994) recorded a lower H' index value at the exposed site (1.606 bits/individual), and higher value for the sheltered site (3.817 bits/individual).

The number of common species between the two locations was very high, which was reflected in the value for the Jaccard index. However, García-Lopez (1994) reported a lower index (0.375) for these same locations. According to the Morisita-Horn index, the two sites were quantitatively very similar.

The malacologic community of the upper part of middle intertidal zone of two locations with different exposure to waves was found to be very similar, contrary to the proposed hypothesis of this investigation. However, there are some differences that are important to point out. At the sheltered shore, seasonal changes in richness and diversity were greater despite the lesser variation in its dominant community. At the exposed shore, these changes were more gradual over time despite a greater variation in the dominant community, reflecting a greater stability of the malacologic community at this site.

ACKNOWLEDGMENTS

The authors thank CONACYT for the support offered for the development of this research and Dr. Gorgonio Ruiz Campos for his review of the manuscript and valuable comments. Dr. Enrique Villalando Canchola, provided invaluable help throughout the study. We appreciate the comments and suggestions from Dr. Emilio Michel Morfín and Dr. Victor Landa Jaime. We also thank Dr. Albert Leyva for his help in the preparation of the manuscript.

PHYLOGENETIC RELATIONSHIPS AMONG THE DECABRACHIA CEPHALOPODS INFERRED FROM MITOCHONDRIAL DNA SEQUENCES

XIAODONG ZHENG,^{1*} JIANMIN YANG,^{1,2} XIANGZHI LIN^{1,3} AND RUCAI WANG¹

¹Mariculture Research Laboratory, Fishery College, Ocean University of China, Qingdao, China 266003; ²Marine Fisheries Research Institute of Shandong Province, Yantai, China 264000; ³College of Oceanography and Environmental Sciences, Xiamen University, China 361005

ABSTRACT To clarify phylogenetic relationships among the decabrachia cephalopods, especially the family Sepiidae and Sepiolidae, mitochondrial cytochrome *c* oxidase subunit I (COI) gene and partial 16S rRNA gene were sequenced for 13 species. Phylogenetic analyses were performed by the distance and parsimony method. Coleoids were divided into 2 main lineages, Octobranchia and Decabrachia (including Sepiida, Sepiolida, and Teuthida). In all phylogenetic trees, the monophyly of the Sepiolidae and Sepiidae was supported well, but their rank and position within the Decabrachia were not clear. Based on partial COI rDNA and its amino acid sequences, Parsimony analyses showed Sepiolidae, Sepiidae, and the (*Loligo chinensis*, *Chtenopteryx sicula*) clade from Teuthida were in the same level. Compared with Sepiidae, Sepiolidae was more closely related to Teuthids using 16S rDNA sequences. We are inclined to support the current classification: Sepiolidae and Sepiidae belong to different Orders. According to the phylogenetic analysis, the 2 genera (*Sepiella* and *Sepia*) from the Sepiidae can be distinguished (78% neighbor-joining (NJ); 64% maximum parsimony (MP) in 16S rRNA gene), but do not have visible boundline using COI gene and its amino acid data. This suggests that COI gene may be much fitter to analyze cuttlefish phylogeny at a high taxonomic level (i.e., family), and 16S rRNA gene could be used as a precious tool to analyze taxonomic relationships at the genus level.

KEY WORDS: phylogeny, cephalopods, Decabrachia, COI, 16S rRNA gene

INTRODUCTION

According to Voss (1977), the Sepioidea includes Spirulidae, Sepiidae, Sepiolidae, Idiosepiidae, and Sepiadariidae. To date, the taxon system is still used in China. The position of the Sepiolidae as a sister group of the Sepiidae and the monophyly of the squids are, however, questioned by some scholars (e.g., Berthold & Engeser 1987, Clarke 1988, Boletzky 1999).

Molecular information from DNA data has been used to clarify the relationships among Cephalopods since the 1990s. The nucleotide divergence between sequences of one gene or a portion of gene from the mitochondrial or nuclear genome can be analyzed phylogenetically. Previous DNA sequence diversity and phylogenetic relationships of octopods have been investigated using the mitochondrial cytochrome *c* oxidase subunit I (mtCO I), mtCO II, mtCO III, 16S rRNA gene (Carlini & Graves 1999, Carlini et al. 2001, Bonnaud et al. 1996, Bonnaud et al. 1997, Söller et al. 2000, Alcock & Piertney 2002, Piertney et al. 2003). Anderson (2000) sequenced 2 mitochondrial genes (16S rRNA and CO I) to clarify loliginid phylogeny. Sequence analyses from the 3' end of the mt l-rRNA (16S) gene of decapod cephalopods have shown that this portion of gene was a useful tool for taxonomic relationships at the infrafamilial level (Bonnaud et al. 1994). The COI gene for phylogenetic analysis of the coleoid cephalopods exhibited a high degree of nucleotide sequence variability, with one half of the sites varying in at least one taxon; COI amino acid sequences were highly conserved, but were useful in determining basal-level relationships among the Coleoidea (Carlini et al. 2001).

The cephalopods, especially decapods, are an important and valuable fishery resource in China, South Korea, and Japan (Nesis & Kir 1982, Okutani 1995). For example, *Sepia esculenta*, *Sepiella maindroni* and *Loligo chinensis* are all high commercial species (Dong 1991). A great deal of fundamental and applied researches

on cephalopods, such as fauna, systematics, morphology, embryology, population genetics, and biodiversity have been completed since 1960s (e.g., Lee 1963, Lee 1983, Dong 1993, Lu 1998, Lu 2000, Zheng et al. 2001a, Zheng et al. 2001b, Zheng et al. 2004). There are, however, few documents referring to the molecular evolution and phylogenetics of cephalopods living in the coastal waters of China. In this study 13 cephalopod species are analyzed by the sequence comparison of 16S rRNA and COI gene. The phylogenetic trees are reconstructed. The taxonomic relationships of decabrachia species are discussed.

MATERIALS AND METHODS

Taxon Selection

Eight decabrachia species and two octopus species were sampled for 16S rRNA gene sequence analysis. Representatives of three other cephalopods (*Euprymna scolopes*, Bonnaud et al. 1994; *Chtenopteryx sicula*, *Grimpoteuthis* sp., Anderson 2000) were added to cladistic analysis.

Eight decabrachia species and one octopus species were sampled for the COI gene sequence analysis. Representatives of 4 other cephalopods (*Nautilus pompilius*, Carlini & Graves 1999; *Euprymna scolopes*, Bonnaud et al. 1994; *Chtenopteryx sicula*, *Grimpoteuthis* sp. Anderson 2000) were added to cladistic analysis.

Details on the taxonomic position (following Voss 1977) and origin of the 13 species studied are presented in Table 1.

DNA Extraction, Amplification, and Sequencing

Total genomic DNA was extracted using a CTAB method modified from Winnepenninckx et al. (1993). Regions of the 16S and COI genes were amplified by PCR. The 16S primers sequences were D16SAR 5'-CGC CTG TTT AHY AAA AAC AT-3', D16SBR 5'-CCG GTC TGA ACT CAG MTC AYG T-3' (Anderson 2000). The primers used for the amplification of

References: AN, Anderson F. E. (2000); CA, Carlini, D. B. and Graves, J. E. (1999); BO, Bonnaud, L. Boucher-Rodoni R. Monnerot M. (1994), ZH, the authors. #Genbank accession numbers.

partial COI gene were: HCO2198 (5'-TAA ACT TGA GGG TGA CCA AAA AAT-3') and LCO1491 (5'-GGT CAA CAA ATC ATA AAG ATA TTG-3') from Folmer et al (1994). Amplifications were performed under the following conditions: 120 s at 94 °C, then 30 or 35 cycles (COI and 16S, respectively) of 40 s at 94 °C, 1 min at 50 °C, and 1 min at 72 °C. A total volume of 25 µL reactions consists of 0.5 units of *Taq* (TaKaRa), 0.5 µM each primer, 0.2 µM each dNTP, 2.5–3.5 mM MgCl₂, 2.5 µl of 10× buffer supplied with *Taq* and 4 µl (30–50 ng) of template DNA.

The amplified fragments were purified by the PCR fragment recovery Kit (TaKaRa). Purified products were sequenced directly using the ABI PRISM BigDye Terminator cycle sequencing Ready Reaction Kit and AmplicTaq DNA polymerase with ABI PRISM 377XL DNA sequencer (Applied Biosystem Inc.).

Phylogenetic Analyses

All of the initial sequences were aligned by ClustalX v 1.8 (Thompson et al. 1997). Amino acid sequences of the COI gene were translated using the GENEDOC (Nicholas et al. 1997). The mean nucleotide composition, proportion of transition (ts) by number of the total base substitutions (ts + tv, transitions + transver-

sions) were calculated in MEGA 2 (Kumar et al. 2001). The phylogenetic analyses were performed on both aligned nucleotide sequences and on amino acid sequences, using distance and parsimony methods included in the packages MEGA 2 (Kumar et al. 2001) and PAUP4.0b6 (Swofford 2000). Statistical confidence of a particular cluster of sequences was evaluated by the bootstrap procedure (1,000 resampling replicates).

RESULTS

Genetic Variation of Partial COI Gene Sequence

The percentage proportion of 4 kinds of base pairs (A, C, G, T) was compared with each other. There was no remarkable difference between these species examined. The average content of base pairs in the nine species examined was 28.12%, 17.51%, 15.71%, and 38.60%, respectively. A + T content was also up to 66%, which is in the same range as in the reference species. High A + T content was an obvious characteristic of cephalopod mtDNA sequences. No gaps were found in all of the sequences we analyzed. A total of 281 nucleotide positions were found to be variable (42.4%). One-hundred and ninety-four variable sites were found at

the third position of codon triplet and the percentage was approximately 69% of all variable nucleotides.

The genetic distance ranged from 0.000 to 0.202 among the Sepiidae. *Sepiella maindroni* could not be separated from other species of the family using distance method, although it belonged to *Sepiella* in the traditional taxonomy. The closest taxon with respect to genetic distance was *Sepia latimanus* (0.000), and the most distant was *Sepia aculeata* (0.202). Compared with the data between Sepiidae and Sepiolidae, the distance was 0.191 ± 0.008 (mean \pm SD), slightly closer than between Sepiidae and Teuthida (mainly mentioned Loliginidae and Chtenopterygidae) (0.206 ± 0.007) as well as between Sepiolidae and Teuthida (0.215 ± 0.013). *Nautilus pompilius*, belonging to Nautilida, was the most distant species from the other 12 cephalopods analyzed (0.288 ~0.349).

According to the amino acid sequences, the genetic distance was in the range of 0.000 to 0.0056 within the Sepiidae. *Sepiella maindroni* was grouped with the other cuttlefishes, even though they belong to a different genus in the traditional taxonomy. The farthest distance between *Nautilus pompilius* and other cephalopods (0.119 ~0.178) indicated that the relationship between them was the most remote.

Genetic Variation of Partial 16S rRNA Gene

The length of 16S rRNA gene sequences of the 10 species examined ranged from 500 to 514 base pairs (average 507.5 bp). The average of percentage proportion of A, C, G, and T was 34.25%, 9.83%, 17.93%, and 37.99%, respectively. The content of A + T is up to 72%. The result is similar to the above research of the COI gene sequences for cephalopods.

In the Sepiidae, the genetic distance of 5 species of *Sepia* ranged from 0.030 to 0.045, and become a bit higher with *Sepiella* (0.059 ~0.077). The distance between Sepiidae and Sepiolidae (0.085 ± 0.009) was not significant different from that between Sepiidae and Teuthida (0.090 ± 0.013) or Sepiolidae and Teuthida (0.089 ± 0.012). The longest distance (0.173) was observed between Sepiolidae (*Euprymna scolopes*) and Octopoda (*Octopus variabilis*).

Phylogeny of Cephalopods Based on COI and 16S rRNA Gene Sequence

Phylogenetic Analysis Based on Partial COI and Amino Acid Sequences

The topology structure of phylogenetic trees was similar using the COI and their amino acid sequences, whatever NJ trees and MP trees. The monophyly of the Sepiolidae (98% NJ, 78% MP in Fig. 1; 90% NJ, 74% MP in Fig. 2) and Sepiidae (50% NJ, 58% MP in Fig. 1; 93% NJ, 87% MP in Fig. 2) was well supported. According to NJ analyses, Coleoids were divided into 2 main lineages, Octobranchia and Decabrachia (including Sepiidae, Sepiolidae, and Teuthida). In the Decabrachia clade, 6 species from the Family Sepiidae grouped with 2 species from the Order Teuthida at first, then grouped with the Family Sepiolidae (NJ trees in Fig. 1 and 2), though low levels of bootstrap support were obtained (see asterisk place in Fig. 1 and 2). Parsimony analyses indicated that the Decabrachia was divided into 3 parallel clades (88% MP in Fig. 1; 96% MP in Fig. 2). Within the Sepiidae clade, *Sepiella* (*S. maindroni*) and *Sepia* could not be divided clearly; and the groups from 5 species in *Sepia* were not consistent with morphologic evidence, which belong to 3 different species complexes (Khromov 1998).

Phylogenetic Analysis Based on Partial 16S rRNA Gene Sequence

Both MP and NJ analyses provided strong bootstrap support values for the monophyly of the Coleoid cephalopods (98% MP and 98% NJ), and the monophyly of the Family Sepiidae (64% MP and 78% NJ) as well as Family Sepiolidae (95% MP and 96% NJ) (Fig. 3). Within the Decabrachia clade, Sepiolidae was more closely related with Teuthida (54% MP and 72% NJ). *Sepiella* and *Sepia* were clearly separated (64% MP and 76% NJ). Though the topology structure (NJ tree) in *Sepia* clade was consistent with the classification of species complexes of Sepiidae, bootstrap support values were very low (<50%).

DISCUSSION

Previous investigations of coleoid systematics have attempted to determine relationships within the Sepiida, Octopoda, and Teuthida through phylogenetic analysis of morphologic and molecular character data. Most recently, Carlini and Graves (1999)

conducted a higher-level analysis of the coleoid cephalopods. Consistent with them, our results suggest that the coleoids can be divided into 2 main lineages: the Octobranchia and the Decabrachia.

According to the classification of cephalopod taxa (Voss 1977), the Order Sepioidea was comprised of 5 families Spirulidae, Sepiolidae, Sepiidae, Sepiadariidae, and Idiosepiidae (Fig. 4). Although the COI and 16S rDNA data well supported the monophyly of the Decabrachia, we could not confirm the validity of the order Sepioidea. Several studies have questioned this order (Clarke 1988, Bonnaud et al. 1996, Bonnaud et al. 1997, Sweeney & Roper 1998, Carlini & Graves 1999) (see Fig. 4). Bonnaud et al. (1994) analyzed phylogeny of decapod cephalopods based on 3' end of 16S rDNA nucleotide sequences, and demonstrated that Sepioids were clearly excluded from the order, and the position of the Spirulidae required further clarification. Referring to paleontology and neontology evidences of cephalopods, Clarke (1988) pointed out that the five families belonged to two orders, that is the Order Sepiida was composed of Sepiidae, Spirulidae and Sepia-

dariidae; Sepiolidae and Idiosepiidae belonged to the Order Sepiolida. Sweeney and Roper (1998) listed the currently accepted classification of the recent Cephalopoda and addressed that the five families belonged to three orders. Boletzky (1999) indicated that they should be subject to four orders, and the Superorder Decabrachia included 5 orders, Spirulida, Sepiida, Sepiolida, Idiosepiida, and Teuthida (see Fig. 4). Carlini and Graves (1999) pointed out that the Sepioidea were polyphyletic. In all phylogenetic trees, the monophyly of the Sepiolidae and Sepiidae was supported well, but their rank and position within the Decabrachia were not clear. Based on partial COI and its amino acid sequences, Parsimony analyses showed Sepiolidae, Sepiidae as well as the (*Loligo chinensis*, *Chtenopteryx sicula*) clade from Teuthida were in the same level (88% in Fig. 1 and 96% in Fig. 2). Compared with Sepiidae, Sepiolidae was more closely related to Teuthids (72% NJ and 54% MP) using 16S rDNA. We are inclined to support the current classification: Sepiolidae and Sepiidae belong to different orders. As for the rank and position of other families (e.g., Idi-

Figure 3. NJ phylogenetic tree and MP tree based on based on 16S rRNA gene data. Boldfaced numbers above branches are bootstrap support values (1000 replicates). *Grimpoteuthis* sp. was used as distant outgroup species. (1) Sepiidae, (2) Sepiolidae, (3) Teuthida, (4) Octopodidae.

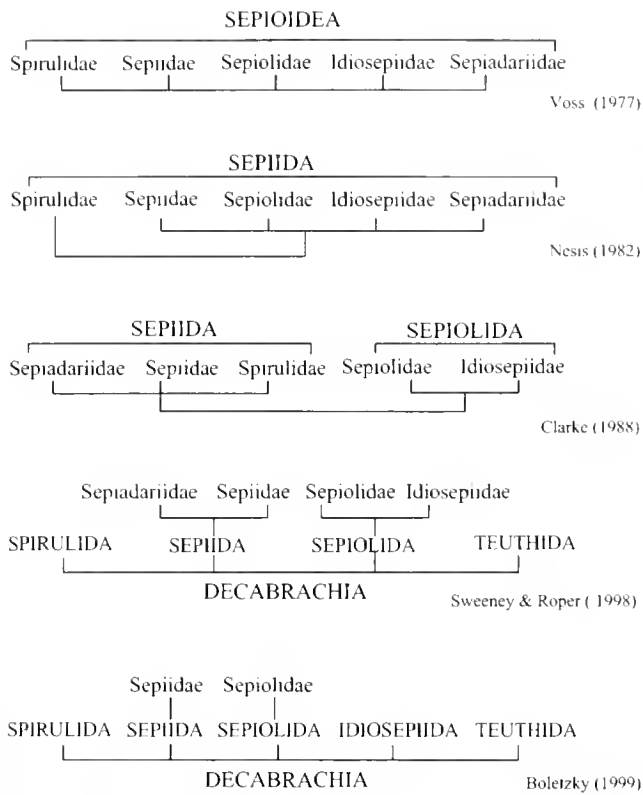

Figure 4. Sepiid relationships with other taxa according to various authors. Ordinal rank indicated by capital letters.

osepiidae, Spirulidae, etc), such researches will be carried out further and testify these families' phylogenetic relationship.

According to the COI gene and amino acid sequence data, the family-level relationship was exhibited clearly, but the genus *Sepiella* (*S. maindroni*) was grouped with other species from *Sepia* (see Fig. 1 and 2). *Sepiella* was obviously separated from the *Sepia* groupings based on the 16S rDNA sequences (see Fig. 3), which demonstrated that they belonged to two separate genera. It shows possibility that mtDNA sequence fragments (e.g., 16S rDNA, COI) with different evolutionary rate are fit for different taxa phylogeny. The 16S rDNA of Cephalopods is a precious tool to analyze taxonomic relationships at the genus level, and COI gene is fitter at the family level. Of course, 3 species complexes within the genus *Sepia* were not well supported in all the MP trees. The recognition of subgeneric rank in *Sepia* is not used because more analyses on morphologic, behavioral, biochemical, and molecular data are needed to resolve the question (Lu 2004, pers. comm.). We will examine more extensive sequence data of the species of *Sepia* for more refined information of species complexes or subgeneric rank.

ACKNOWLEDGMENTS

The authors thank Professor C. C. Lu for valuable suggestions about classification of Cephalopoda, and to Ms. C. W. Ho for help on sequence data analysis. The authors also thank X. D. Du, M. Z. Zeng, W. Z. Chen, and J. M. Zhao, for assistance in the collection of samples, and Ms. Y. L. Wu for helpful comments on the manuscript.

COMPARISONS BETWEEN THE REPRODUCTIVE BIOLOGY OF FEMALES OF TWO SPECIES OF DEEP SEA CRABS THAT LIVE IN DIFFERENT WATER DEPTHS

KIM D. SMITH, IAN C. POTTER* AND S. ALEX HESP

Centre for Fish and Fisheries Research, School of Biological Sciences and Biotechnology, Division of Science and Engineering, Murdoch University, Murdoch, Western Australia, 6150, Australia

ABSTRACT The reproductive biology of females of *Hypothalassia acerba* and *Chaceon bicolor* off the lower west coast of Australia, and of the former species off the southern coast of Western Australia, are compared. The trends exhibited throughout the year by the prevalence of different stages in ovarian development and of females bearing eggs and egg remnants, together with those of relative gonad weight, demonstrate that the reproduction of *H. acerba* on the lower west coast is highly seasonal. Thus, overall, gonads matured progressively between July and December and oviposition occurred between January and March. The characteristics of *H. acerba* on the south coast differed in the following ways from those on the lower west coast: (1) no ovigerous females and only two females with egg remnants were caught; (2) late yolk granule oocytes were not developed in ovaries until females had reached a larger size; and (3) investment in gonadal development was less. These results strongly indicate that conditions on the south coast are not as conducive for ovarian development and reproduction and that females migrate from the south to lower west coast for spawning. In contrast to *H. acerba*, *C. bicolor* reproduces throughout the year on the lower west coast, presumably reflecting its occupancy of far deeper waters where environmental conditions vary less during the year. Although the mean weights of ovigerous females of *H. acerba* and *C. bicolor* were not significantly different ($P > 0.05$), the mean fecundity of the former species (356,210) was significantly greater ($P < 0.001$) than the latter species (192,070). The greater fecundity of *H. acerba* may reflect adaptations by this seasonal spawner to optimize egg production during its short breeding season.

KEY WORDS: crabs, reproduction, spawning period, water depth, seasonality, gonadal investment

INTRODUCTION

Three species of deep sea crab are fished commercially in Western Australian waters, namely the champagne crab *Hypothalassia acerba* Koh and Ng, the crystal crab *Chaceon bicolor* Manning and Holthuis, and the king crab *Pseudosquilla gigas* Lamarek (Anonymous 2002). Based on catches obtained by commercial fishers, the distribution of *H. acerba* ranges from a latitude at least as far north as about 27°S on the west coast, southwards, and then eastwards along the south coast to a longitude of at least 129°E (Anonymous 2002). Although *C. bicolor* occurs in the same geographical region as *H. acerba*, its distribution in Western Australia extends further north to a latitude of about 22°S (Melville-Smith et al. in press). In contrast, the distribution of *P. gigas* is essentially restricted to the south coast in Western Australia and extends eastwards across the full length of Australia, including Tasmania, and then northwards on the east coast to about 31°S (Kailola et al. 1993, Gardner 1998).

Recent depth-stratified sampling off the south-western Australian coast has demonstrated that *H. acerba* occurs predominantly in waters where temperatures lie between 13°C and 19°C, the depths range from 200–255 m on the lower west coast, and from 90–200 m on the south coast (Smith et al. 2004a). Temperatures recorded during commercial fishing for *C. bicolor* show that on the lower west coast of Australia this species typically occurs in waters of 4°C to 6.5°C (K. Smith unpublished data) and at water depths of 450–1220 m (Melville-Smith et al. in press); thus this species is located further offshore than *H. acerba*. *Pseudosquilla gigas* is found in waters of 11°C to 17°C and at depths of 120–340 m (Levings et al. 1996).

The commercial fisheries for *H. acerba* and *C. bicolor* in Western Australia started to develop during the late 1990s (Anonymous 2002). However, in contrast to the situation with *P. gigas* (see Levings et al. 1996, 2001, Gardner 1997, Gardner & Williams

2002), no biological studies have been conducted on the spawning period and location and fecundity of either of these two species.

The stages in development of the ovaries of several species of deep sea crabs belonging to the Geryonidae (e.g., *Chaceon quinquedens*, Smith; *Chaceon maritae*, Manning & Holthuis; and *Chaceon affinis*, Milne Edwards & Bouvier), have been described based on their macroscopic appearance and, in some cases, on the stages of maturation of their oocytes, as determined from histologic sections (Haefner 1977, Melville Smith 1987a, Fernández-Vergaz et al. 2000, López Abellán et al. 2002). No such combined macroscopic and histologic studies have been carried out on any deep sea species of the Eriphiidae, the family to which *H. acerba* belongs. Although some deep sea crab species, such as *Chaceon femeri* (Manning & Holthuis), have an annual reproductive cycle (see Hastie 1995), no clear seasonal fluctuations in reproductive patterns were detected in *C. maritae* (Melville-Smith 1987a) and *C. quinquedens* (Wigley et al. 1975, Haefner 1978). It was proposed by Melville-Smith (1987a) that the absence of a distinct reproductive cycle in *C. maritae* was attributable to the absence, in the deep waters in which this species is found, of changes in day length and temperature and other potential environmental reproductive triggers.

The aims of this study are as follows. (1) Describe, on the basis of their macroscopic appearance, the sequential stages in the development of the ovaries of *H. acerba* and use histologic sections to determine the stages of maturation of the oocytes in ovaries at each of those stages. Attention is paid to elucidating whether the criteria developed for categorizing the ovarian stages of *H. acerba* were the same as those we developed concomitantly for *C. bicolor* and those described for other species of deep sea crab. (2) Use the trends exhibited throughout the year by the monthly prevalences of female crabs with ovaries at different stages in development and of females bearing either eggs or egg remnants, together with those of the mean monthly gonad weights of females, to determine the timing of reproduction in these two species. Particular emphasis is placed on testing the hypothesis that, as *H. acerba* lives in far

*Corresponding author. E-mail: i.potter@murdoch.edu.au

shallower waters than *C. bicolor*, and thus in an environment which undergoes a greater degree of seasonal change and particularly in water temperature, it is far more likely to reproduce seasonally. (3) Determine the fecundities of *H. acerba* and *C. bicolor* and their relationships to the body size and body weight of these species. (4) Establish whether aspects of the reproductive biology of *H. acerba* on the lower west and southern coasts of Western Australia exhibit similar patterns. Because preliminary analyses indicated that *H. acerba* invests less in gonadal development on the south than west coasts, we examined whether the relative ovarian weights and diameters of the mature oocytes of females on the two coasts differed.

MATERIALS AND METHODS

Collection of Samples

Samples of *Hypothalassia acerba* were randomly selected from trap catches taken by commercial fishers off the lower west and south coasts of Western Australia between ca. 30°10'S, 114°30'E and 32°30'S, 114°60'E and between 34°40'S, and 115°40'E and 34°45'S, 119°30'E, respectively. *Chaceon bicolor* was obtained from the trap catches taken by commercial fishers off the lower west coast of Australia between 24°15'S, 112°15'E and 33°04'S, and 114°23'E. The reader is referred to Smith et al. (2004b) for details of the sampling gear. The samples of *H. acerba* and *C. bicolor*, which were collected at regular intervals between July 1999 and April 2002 and between January 2000 and December 2003, respectively, were pooled with additional smaller samples that were collected by the same methods and purchased regularly from fish markets. This ensured that the monthly prevalences of females at different stages in development and mean monthly relative gonad weights were derived from data for individuals in catches representing, on at least one occasion, each calendar month of the year in the case of each species in the waters in which they were sampled.

Laboratory Processing

The carapace length (CL) and wet weight (W) of each female of *H. acerba* and *C. bicolor* were recorded to the nearest 1 mm and 1 g, respectively. For each female, a record was kept of the relative size and shape of the gonopores and whether mating abrasions were present around their gonopores. Most females of *C. bicolor* with a CL <100 mm possessed elliptical gonopores, indicating that they had not mated, a conclusion consistent with the absence of mating scars in the region of their gonopores (see also Melville-Smith 1987a, Haefner 1977). Although the gonopores of female *H. acerba* did not exhibit such a conspicuous dichotomy in shape as those of *C. bicolor*, the individuals of this species with a CL <ca. 70 mm had relatively very small gonopores and, unlike many larger individuals, they never bore mating scars in the region of their gonopores. The first and small group of *H. acerba* were thus considered not to have mated, which is consistent with the ovaries of all such individuals being at stage I (see Table 1 in results for description of the characteristics of the different stages in ovarian development).

The ovary of each female was removed and allocated to a numerical developmental stage on the basis of macroscopic criteria (see Results). The stages in development of the testes and vas deferentia were recorded during another study aimed at determin-

ing the size at maturity of the males of these two species (Smith et al. in prep.). The ovary of each female of *H. acerba* and *C. bicolor* was weighed to the nearest 0.1 g. The mean monthly ovarian weights ($\pm 95\%$ CIs) at standardized CLs were determined for *H. acerba* on the lower west and south coasts and for *C. bicolor* on the former coast using analysis of covariance (ANCOVA) of the natural logarithm of the gonad weight as the dependant variable, month as a fixed factor and the natural logarithm of the CL as a covariate. Note that the standardized CL was calculated separately for the lower west and south coast assemblages of *H. acerba* and the lower west-coast assemblage of *C. bicolor*. These constant CLs were a default value calculated by the ANCOVA. ANCOVA was also used in the manner (mentioned earlier) to calculate the mean gonad weight ($\pm 95\%$ CIs) for *H. acerba* with ovaries containing previtellogenic, early vitellogenic, and late vitellogenic oocytes on the lower west and south coasts. The standardized CL was calculated separately for each of these three developmental stages, but was common for a given stage on the two coasts. Data for the small individuals that were considered not to have mated were not used when calculating the monthly prevalences of females with ovaries at different stages in development, the mean monthly gonad weights for females at a standardized CL, and the mean gonad weights for west and south coast *H. acerba* with ovaries at different stages in development (see Figs. 2, 3, 4, and 5 in Results).

The method of Melville-Smith (1987a) was used for determining the fecundity of *H. acerba* and *C. bicolor*. Thus, alternate pleopods were removed from the abdomen of each ovigerous female and soaked for 1–4 h in 0.5 M NaOH to facilitate the separation of eggs from the pleopod setae. All of the eggs removed from each crab were pooled, oven dried at 70°C for 24 h and then weighed to the nearest 0.001 g. Subsamples of ca. 0.1 g of eggs (= ca. 300 eggs) were then weighed and counted, and the average weight of a single egg in each subsample was calculated. When estimates of the weight of a single egg in three subsamples differed by less than 5%, the mean of those weight estimates was then used, in conjunction with twice the weight of all eggs removed, to estimate the fecundity of the crab.

The right posterior side of the ovary was removed from up to 20 females of both species in each season, ensuring that these subsamples covered the full size range of those species in the total catch in each season. The ovarian material was fixed in 4% glutaraldehyde in a 0.025 M phosphate buffer solution (pH 7.0), dehydrated in a series of increasing concentrations of ethanols, embedded in paraffin wax, sectioned transversely at 6 μ m, and stained with Mallory's trichrome. The ovarian material was fixed in glutaraldehyde because it was not fixed well by traditional fixatives used for light microscopy, such as Bouin's and 10% formalin. The smallest and largest diameters of oocytes of *H. acerba* and *C. bicolor* at different developmental stages sectioned through their nuclei were measured to the nearest 5 μ m. The smallest and largest diameters of each oocyte were then averaged.

In addition to the earlier mentioned laboratory processing of crabs, the senior author also recorded, when on board fishing vessels, the total number of mature female crabs caught and the percentage of both ovigerous females and of females with egg remnants attached to their pleopods. Note that, due to inclement weather, the commercial fisher with whom we mainly worked did not operate in September in the deep waters off the lower west coast of Australia where *C. bicolor* is found, and thus there are no data on the above variables for that month.

RESULTS

Ovarian Maturation Stages

Based on their macroscopic appearance, the ovaries of the females of *Hypothalassia acerba* and *Chaceon bicolor* each followed essentially the same pattern of development (Table 1). Thus, for both species, six sequential stages were recognized (Table 1; Fig. 1). As they progress from stages I to IV, the ovaries increase progressively in size and change color (see Figs. 1a to d). However, the colors of the ovaries of the two species at stages III and IV differ. In both species, ovaries at stages V and VI are flaccid and could not be separated macroscopically.

At a histologic level, cortical alveolar oocytes first appeared in stage II ovaries of *H. acerba* (see Figs. 1a, b), and the presence of early and late yolk granule oocytes characterized stage III (see Fig. 1c) and IV ovaries (see Fig. 1d), respectively. Ovaries of recently spent females (stage V) of *H. acerba* contained some atretic oocytes (see Fig. 1e), whereas those of spent-recovering (stage VI) females possessed no such oocytes but did contain numerous early previtellogenic oocytes (see Fig. 1f). The histologic characteristics of the ovaries of *C. bicolor* are essentially the same as those shown for *H. acerba* in Figures 1a to f. However, the mean diameters of the mature oocytes, as measured in stage IV ovaries, are significantly greater ($P < 0.001$) for *C. bicolor* than *H. acerba*.

Comparisons of the macroscopic and microscopic characteristics of our ovarian stages for *H. acerba* and *C. bicolor* with those of Haefner (1977) demonstrate that the ovaries of the former two species undergo the same pattern of development as *Chaceon quinquedens*. However, the maximum diameter of the oocytes in our stage I (70 μm) is far less than that recorded by Haefner (1977) for his first stage for *C. quinquedens* (172 μm) and yolk granule oocytes are already present in his stage II whereas they do not appear until stage III of our categorization for *H. acerba* and *C. bicolor*. In essence, Haefner (1977) did not recognize the presence of the early stage we have termed virgin/immature resting. However, that stage was recognized by de Lestang et al. (2003) in their description of ovarian development in *Portunus pelagicus* (Linnaeus) in inshore waters in Western Australia. Furthermore, unlike the study of Haefner (1977), our histologic staging criteria distinguish recently-spent ovaries from spent-recovering ovaries, which is useful for obtaining an idea of how recently ovulation had occurred.

Monthly Trends in Reproductive Indices

On the lower west coast, the prevalence of female *H. acerba* with ovaries containing late vitellogenic oocytes was greatest in September to February, during which months their contributions ranged from 58% to 76%, and was least in March to June when

TABLE 1.

Macroscopic and microscopic characteristics of sequential stages in ovarian development of *Hypothalassia acerba* and *Chaceon bicolor*. Range in oocyte diameters at each stage of development are provided. Scheme has been adapted from that of Haefner (1977).

Ovary Stage	Macroscopic Description	Histological Description
Stage I Virgin/immature resting	Ovaries small but generally visible macroscopically, thin and 'H' shaped. (Shape is maintained for all latter stages except stage IV). Oocytes not visible through ovarian wall. Color varies from pale grey to ivory.	Ovaries contain oogonia and small previtellogenic oocytes (chromatin nucleolar and perinucleolar oocytes). Connective tissue and oocytes stain blue with Mallory's trichrome. For <i>H. acerba</i> , oogonia 5–10 μm and small previtellogenic oocytes 10–60 μm . For <i>C. bicolor</i> , oogonia 5–10 μm and small previtellogenic oocytes 10–70 μm .
Stage II Developing	Ovaries always visible macroscopically, larger than stage I and slightly dorso-ventrally compressed. Ovaries beginning to displace hepatopancreas. Oocytes not visible through ovarian wall. Color varies from ivory to white.	Ovaries contain all oocyte stages present in stage I together with cortical alveolar oocytes. Cortical alveolar oocytes 60–200 μm in <i>H. acerba</i> , 70–210 μm in <i>C. bicolor</i> . Cortical alveolar oocytes stain blue with Mallory's trichrome, except for their lipid droplets and nucleoli, which stain dark red.
Stage III Maturing	Ovaries larger than at stage II and outer membrane has wrinkled appearance. Oocytes not visible through ovarian wall. Ovaries are pale pink in <i>H. acerba</i> , but range from very pale yellow to yellowish orange in <i>C. bicolor</i> .	Large numbers of early yolk granule oocytes present. Yolk granules in peripheral region of oocyte cytoplasm. Yolk granules stain orange with Mallory's trichrome and are larger than lipid droplets. For <i>H. acerba</i> , yolk granule oocytes are 160–270 μm and for <i>C. bicolor</i> are 140–390 μm .
Stage IV Mature	Ovaries larger than at stage III and consequently are no longer 'H-shaped'. Ovarian wall more folded. Oocytes visible through ovarian wall. Ovaries pink to red in <i>H. acerba</i> and brown to purple in <i>C. bicolor</i> .	Large numbers of late yolk granule oocytes. Yolk granules distributed throughout cytoplasm. For <i>H. acerba</i> yolk granule oocytes are 200–480 μm and for <i>C. bicolor</i> 350–560 μm .
Stage V Recently spent	Ovaries similar in appearance to stage II, but more flaccid and yellowish-grey in colour	Ovary contains mainly connective tissue. Some yolk granule oocytes present and undergoing atresia.
Stage VI Spent-recovering	Same as stage V.	Ovaries comprise mainly connective tissue and numerous small previtellogenic oocytes.

Figure 1. Histologic sections of ovaries of *H. acerba* at (a) stage I, (b) stage II, (c) stage III, (d) stage IV, (e) stage V, and (f) stage VI. a, atretic oocyte; ca, cortical alveolar oocyte; ct, connective tissue; eyg, early yolk granule; o, oogonia; lyg, late yolk granule; pv, previtellogenic oocyte. Scale bar = 200 μ m.

their monthly contributions ranged from 11% to 50% (Fig. 2a). The prevalence of female crabs with ovaries containing only previtellogenic oocytes was less than 12% in each month from September to February and in April and only exceeded 30% in March and August. Small numbers of spent females were collected between January and March and in May. The mean monthly gonad weight of *H. acerba*, standardized to a constant CL of 94.7 mm, rose progressively from 11.5 g in July to between 25.2 and 28.6 g in October to December, and then it declined sequentially to between 4.9 and 8.3 g in March to May (see Fig. 2b). The prevalence of female *H. acerba* bearing egg remnants declined sequentially from 12% in July to zero or close to zero in October to January before rising progressively to 21% in May. Small numbers of ovigerous females were caught in February, March, and May (see Fig. 2c) and a commercial fisher provided six ovigerous females and two females with egg remnants, which he had caught in January 2000.

On the south coast, the prevalence of female *H. acerba* containing late vitellogenic oocytes and the mean monthly gonad

weights, standardized to a common CL of 95.2 mm, peaked in September (Figs. 3a, b). The prevalence of *H. acerba* with ovaries containing late vitellogenic oocytes never exceeded 47% in any month other than September and the prevalence of ovaries with previtellogenic oocytes exceeded 50% in 5 months (see Fig. 3a). Samples from the south coast yielded no ovigerous females and only two females bearing egg remnants, both of which were caught in August.

The prevalences of females of *C. bicolor* with ovaries containing late vitellogenic oocytes were greater in July to December than in January to April and in June (Fig. 4a). The mean monthly gonad weights, standardized to a constant CL of 110.0 mm, peaked at 42.2 g in September and 43.1 g in December before declining to 11.6 g in February, increasing to 37.1 g in May and then declining to 8.8 g in June (see Fig. 4b). Ovigerous females were caught in each of the 11 calendar months in which samples were obtained and females bearing egg remnants were found in 6 of those months (see Fig. 4c). The mean gonad weight \pm 95% CIs, standardized to a constant CL, did not differ significantly ($P > 0.05$) between the

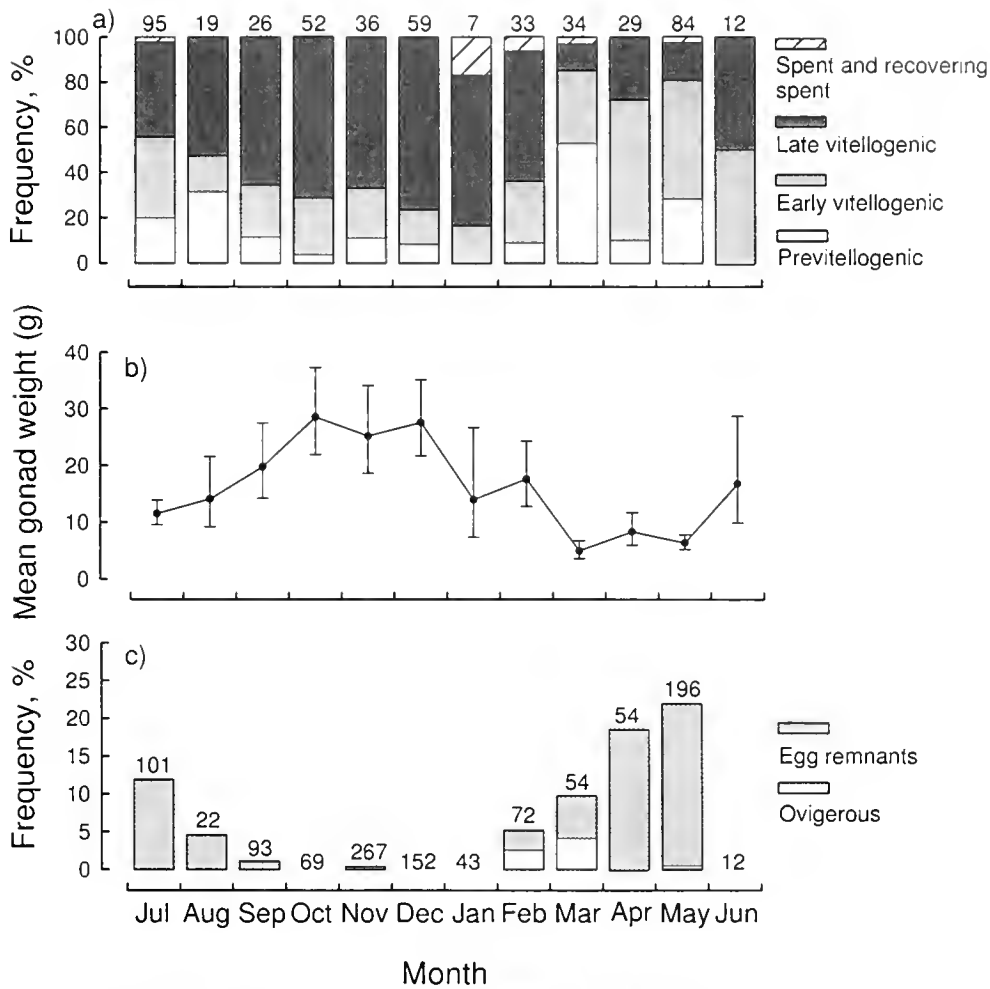

Figure 2. Monthly data for female *Hypothalassia acerba* on the lower west coast of Australia. (a) Frequency of occurrence of crabs at different stages of development, (b) mean gonad weights $\pm 95\%$ CIs standardized to a constant CL of 94.7 mm, as selected by ANCOVA and (c) frequency of occurrence of crabs with eggs and egg remnants. In this Figure and Figures 3 and 4, the sample sizes for each month in (b) are the same as those given in (a).

assemblages on the lower west and south coasts when the females contained ovaries with either previtellogenic or early vitellogenic eggs (Fig. 5). In contrast, the mean gonad weight $\pm 95\%$ CIs for females of *H. acerba* with ovaries containing late vitellogenic oocytes was significantly greater ($P < 0.001$) for the assemblage on the lower west coast, 26.4 ± 1.71 g, than that on the south coast, 16.0 ± 1.85 g (see Fig. 5).

The relationships between gonad *W* and *CL* of west coast and south coast females of *H. acerba* with ovaries containing late vitellogenic oocytes (Fig. 6) are described by the following equations.

West coast: $\ln(W) = 2.561\ln(CL) - 8.130$; $P < 0.001$, $R^2 = 0.240$, $n = 228$

South coast: $\ln(W) = 6.430\ln(CL) - 26.311$; $P < 0.001$, $R^2 = 0.442$, $n = 34$

Although none of the females of *H. acerba* from the south coast, which had *CL*s < 90 mm, contained ovaries with late vitellogenic oocytes, many females of *H. acerba* from the lower west coast with *CL*s of 75 to 90 mm possessed ovaries with oocytes at this advanced stage. The use of ANCOVA demonstrated that, in

the case of *H. acerba* for a standardized selected *CL*, the mean gonad weight of crabs was significantly greater on the lower west coast than south coast ($P < 0.001$).

To enable predictions of *CL* from *W* and vice versa for *H. acerba*, the regression equations relating these 2 variables are:

West coast: $\ln(W) = 2.809\ln(CL) - 6.400$; $P < 0.001$, $R^2 = 0.946$, $n = 581$

South coast: $\ln(W) = 2.768\ln(CL) - 6.128$; $P < 0.001$, $R^2 = 0.893$, $n = 185$

The mean lengths ($\pm 95\%$ CIs) of females from the lower west (93.8 ± 2.02 mm) and south coasts (93.0 ± 1.39 mm) were not significantly different ($P > 0.05$) when the individuals contained previtellogenic oocytes, whereas the corresponding values of 94.7 ± 0.91 mm and 99.1 ± 1.37 mm for females with late vitellogenic oocytes on those two coasts were significantly different ($P < 0.001$). These differences are reflected in the fact that the distributions of the *CL*s of female *H. acerba* on the south coast were located more to the right than those on the lower west coast in the case of females with late vitellogenic oocytes, whereas this was not so with females with previtellogenic oocytes (Fig. 7a, b).

Figure 3. Monthly data for female *Hypothalassia acerba* on the south coast of Australia. (a) Frequency of occurrence of crabs at different stages of development and (b) mean gonad weights ± 95 CIs standardized to a constant CL of 95.2 mm, as selected by ANCOVA.

The mean diameters ($\pm 95\%$ CIs) of late vitellogenic oocytes of *H. acerba* from the lower west coast ($357.7 \pm 10.79 \mu\text{m}$, $n = 342$) and south coast ($370.3 \pm 8.16 \mu\text{m}$, $n = 134$) were not significantly different ($P > 0.05$).

The fecundities of *H. acerba* ranged from 202,295 to 488,758 for crabs with CLs of 90 mm and 102 mm, respectively. The minimum and maximum fecundities for *C. bicolor* were 15,592 and 288,512 respectively, for crabs with CLs of 98 and 133 mm respectively. The mean fecundities ($\pm 95\%$ CIs) of *H. acerba* (i.e., $356,210 [\pm 64,297]$) and *C. bicolor* (i.e., $192,070 [\pm 33,640]$), were significantly different ($P < 0.001$). Although the mean body weights ($\pm 95\%$ CIs) of the ovigerous females of *H. acerba* used for the above fecundity estimates (i.e., $587.4 [\pm 96.5 \text{ g}]$) were substantially less than that of *C. bicolor* (i.e., $651.9 [\pm 61.3 \text{ g}]$), those means were not significantly different ($P > 0.05$). The relationships between fecundity (F) and the CL and wet W of the two species are shown in Figures 8a to d and are described by the following regression equations:

Hypothalassia acerba

$$\ln F = 3.44 \ln(CL) + 1.235, P < 0.05, R^2 = 0.486, n = 10$$

$$F = 0.005W + 0.608, P < 0.05, R^2 = 0.569, n = 10$$

Chaceon bicolor

$$\ln F = 2.957 \ln(CL) + 1.686, P < 0.05, R^2 = 0.127, n = 40$$

$$F = 0.003W + 0.1572, P < 0.05, R^2 = 0.260, n = 40$$

DISCUSSION

Comparisons Between *Hypothalassia acerba* on the West and South Coasts

The trends exhibited by the three reproductive variables recorded for the females of *Hypothalassia acerba* on the lower west coast of Australia were consistent with each other and clearly imply that reproduction in this deep sea species is highly seasonal. Thus, the increase in the prevalence of females with ovaries containing late vitellogenic oocytes between July and October and subsequent leveling off to December was paralleled by a progressive rise and then leveling off in the mean monthly relative gonad weights. Likewise, the subsequent decline in the prevalence of females with this category of advanced ovary between December and March was accompanied by a pronounced decline in the mean monthly relative gonad weights. Furthermore, spent females were found in the short period of January to March, which yielded most of the ovigerous females obtained during this study. It is also highly relevant that the prevalence of female *H. acerba* bearing egg remnants rose progressively from zero or low levels in October to January to peak in May and subsequently declined sequentially to zero between July and October. The consistent trends exhibited by the monthly data for the three reproductive variables strongly suggest that oviposition occurs mainly in January to March.

The patterns exhibited by the reproductive variables for female *H. acerba* on the south coast of Western Australia differed markedly from those displayed by this species on the lower west coast. Thus, on the south coast, the prevalence of females with late vi-

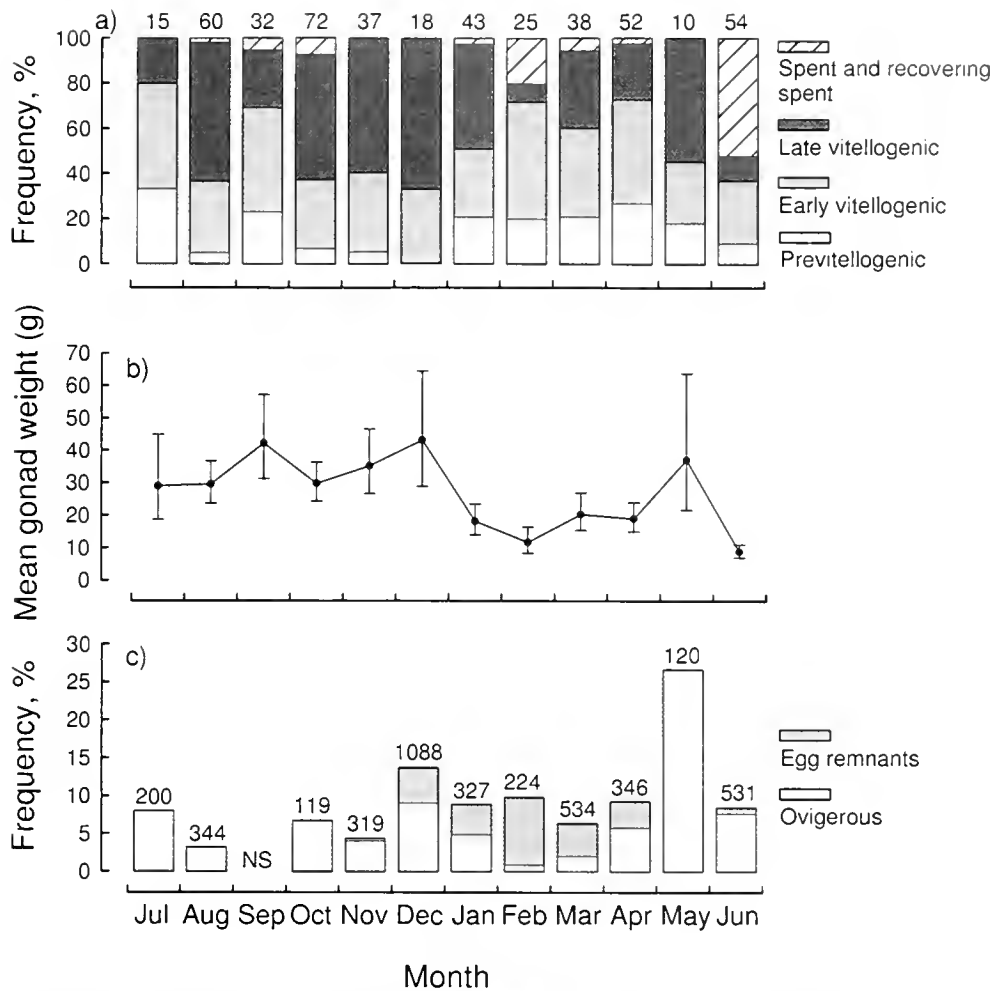

Figure 4. Monthly data for female *Chacon bicolor* on the lower west coast of Australia. (a) Frequency of occurrence of crabs at different stages of development and (b) mean gonad weights $\pm 95\%$ CIs standardized to a constant CL of 110.0 mm, as selected by ANCOVA and (c) frequency of occurrence of crabs with eggs and egg remnants. NS, not sampled.

tellogenic oocytes and the mean monthly relative gonad weights both peaked in September rather than December and the overall prevalence of females with ovaries containing previtellogenic oocytes was far higher. Moreover, no ovigerous female crabs and only two females with egg remnants were collected on the south coast. This strongly suggests that very little reproduction occurs on the south coast.

The possibility that the lack of capture of ovigerous females of *H. acerba* on the south coast is due to females moving inshore prior to oviposition, as occurs, for example, with *Chaceon affinis*, *Chaceon quinquedens*, *Chaceon maritae*, and *Chionoectes opilio* (Fabricius) (Haefner 1978, Melville-Smith 1987a, Comeau et al. 1998, Hastie 1995, López Abellán et al. 2002) seems unlikely. This conclusion is based on the results of our stratified sampling in sequential water depth intervals from 35 m to 365 m, which showed that the females and males of *H. acerba* were both largely concentrated in a relatively narrow range of water depths of 200–255 m off the lower west coast and of 90–200 m off the south coast, and that no crabs were caught in water depths of 35 m (Smith et al. 2004a). However, it is relevant that, although the catches of *H. acerba* on both coasts contained a greater number of

males than females, that difference was substantially greater on the south coast (Smith et al. 2004a). The earlier mentioned data on *H. acerba* suggest that, at some stage prior to oviposition, the females of *H. acerba* on the south coast typically migrate eastwards and then northwards on the lower west coast where they extrude their eggs.

The conclusion that the females of large and maturing *H. acerba* undergo considerable migratory movements is consistent with the observation that such movements are undertaken, in particular, by mature females of some other species of deep sea crabs (e.g., *Chaceon fenneri*, *C. quinquedens*, and *C. maritae* [Melville-Smith 1987b, Lockhart et al. 1990]). Some species of lobster also move substantial distances, including the western rock lobster *Panulirus cygnus* George, along the west coast of Australia (Phillips 1983, Melville-Smith & Cheng 2002). In decapods, these types of movements are often related to reproduction and enable those species to return to their spawning locations as mature adults after they have been transported as larvae or juveniles away from the areas of spawning (e.g., Bennett & Brown 1983, Moore & MacFarlane 1984, Stewart & Kennelly 1988, Groeneveld & Branch 2002). In the context of possible larval movement in south-

Figure 5. Mean gonad weights $\pm 95\%$ CIs for female *Hypothalassia acerba* caught off the lower west versus south coasts and containing ovaries with predominantly previtellogenic, early vitellogenic and late vitellogenic oocytes. The gonad weights of each of the ovarian categories on both coasts were standardized to constant CL as selected by ANCOVA.

western Australia, it is relevant that the important Leeuwin current flows southwards along the lower west coast of Australia and then eastwards along the south coast and extends to a depth of 350 m (Pearce & Griffiths 1991). It is thus proposed that the larvae of *H. acerba* are planktonic, as has been shown by Gardner (1998) to be the case with those of the confamilial *Pseudocarcinus gigas*, and would thus be likely to be transported by this major current from the areas on the lower west coast where spawning occurs. The likelihood of such transport would be enhanced by the fact that the

Figure 6. Relationships between the weights of ovaries containing late vitellogenic oocytes and CL for *Hypothalassia acerba* from both the lower west and south coasts of Western Australia.

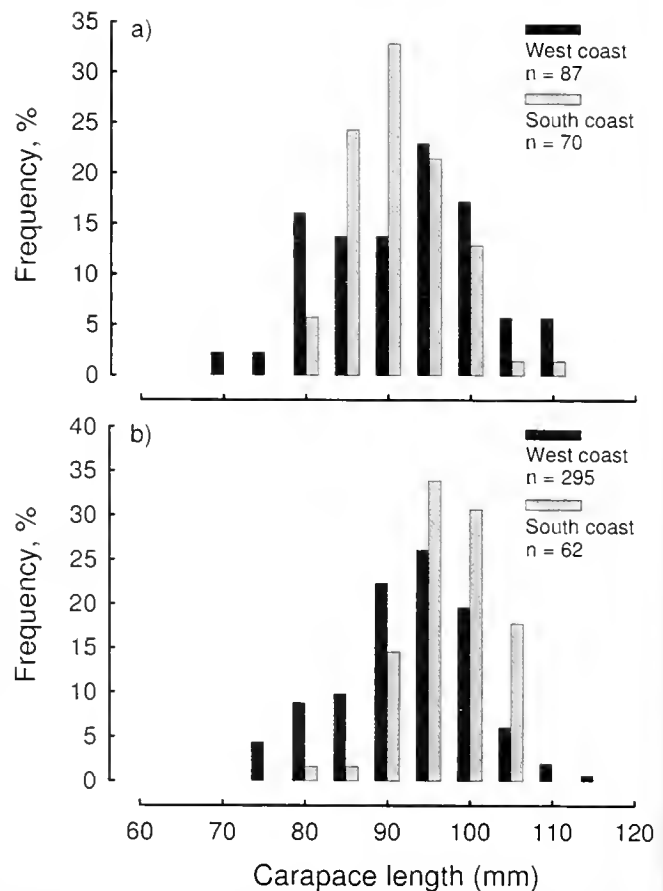

Figure 7. CL-Frequency distributions for female *Hypothalassia acerba* with ovaries containing (a) previtellogenic and (b) late vitellogenic oocytes off the lower west and south coasts of Western Australia.

larvae of *H. acerba* on the west coast are released in autumn, when the Leeuwin current is strongest (Phillips et al. 1991).

Comparisons Between *Hypothalassia acerba* and *Chaceon bicolor*

The trends exhibited by the reproductive variables for *Chaceon bicolor* were far less seasonal than those displayed by *H. acerba*. Thus, although the prevalence of females of *C. bicolor* with ovaries containing late vitellogenic oocytes was high in October to December, it was also relatively high in August and May and, whereas the mean monthly relative gonad weight declined between December and February, it remained high from July to December. More importantly, however, *C. bicolor* with spent/spent-recovering ovaries were caught in 8 months and in each season of the year, thereby indicating that oviposition occurs in most months of the year. This conclusion is consistent with the fact that ovigerous females of *C. bicolor* were caught in each of the 11 months for which samples were obtained for deriving this variable and that, unlike the situation with *H. acerba*, the prevalence of such females did not exhibit a clear pattern of change during the year. The finding that, unlike the situation with *H. acerba* and *P. gigas*, which live in similar water depths (Levings et al. 1996), *C. bicolor* clearly does not reproduce within a restricted part of the year and is consistent with *C. bicolor* occupying far greater depths and thus living in an environment that undergoes little seasonal change. The

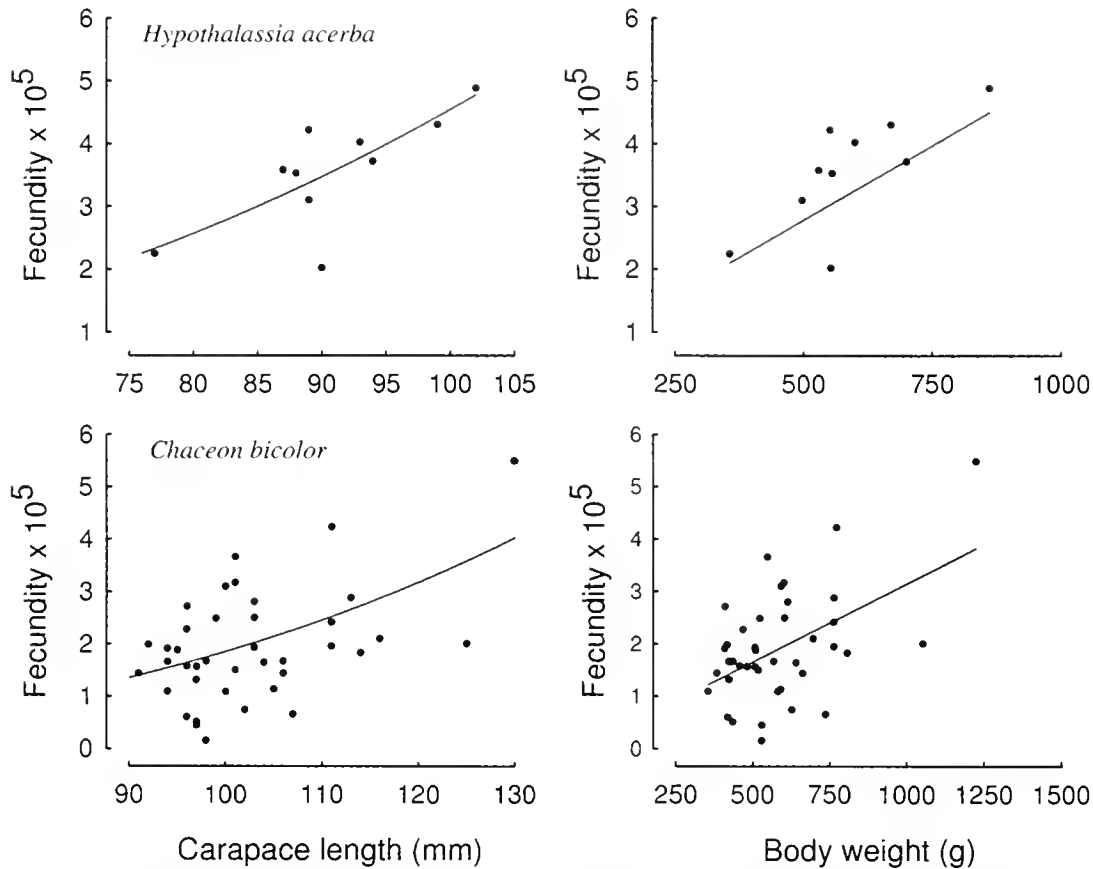

Figure 8. Relationships between fecundity and CL and body weight for *Hypothalassia acerba* and *Chaceon bicolor*.

lack of conspicuous seasonality in the reproduction of *C. bicolor* parallels that found by Melville-Smith (1987a) for *Chaceon maritae*, which likewise lives in deep water. It is also consistent with the fact that the physiologic processes of the majority of organisms living in deep waters do not exhibit seasonality (Tyler 1988).

Investment in Gonadal Development by *Hypothalassia acerba*

It was particularly noteworthy that the mean relative gonad weights of females with late vitellogenic oocytes were far greater for the assemblage on the west coast than for that on the south coast, especially as this did not apply to females with oocytes in earlier stages of development. This strongly indicates that the females of *H. acerba* on the west coast invest less energy in ovarian development than those on the south coast. Furthermore, the lack of a significant difference between the size of the late vitellogenic oocytes of females on the south and lower west coasts implies that any differences in energy allocation to ovarian development on the two coasts is not reflected in differences in an allocation to individual oocytes. From the earlier mentioned data and comparisons, it seems reasonable also to assume that the number of eggs per batch produced by females of *H. acerba* that originated on the south coast are likely to be less than those of the individuals that spent at least most of their life on the west coast.

It is also evident from the data shown in Figure 6 that the females of *H. acerba* on the south coast do not start producing

mature (late vitellogenic) oocytes until they have reached a substantially larger size than those on the west coast. This implies that, in terms of size, the attainment of maturity is delayed on the south coast compared with the west coast.

In summary, our results provide good circumstantial evidence that conditions are less conducive for gonadal development and reproduction by *H. acerba* on the south than lower west coast of Western Australia. Furthermore, they also suggest that maturing females of *H. acerba* migrate from the south coast, which is at the southern and cool end of the distribution of this species, to the west coast for spawning. Reproduction on the lower west coast was shown to occur seasonally in *H. acerba*, but throughout at least much of the year with *C. bicolor*, which occurs in far deeper water and thus where environmental conditions remain more constant during the year. The seasonality of reproduction by *H. acerba* is accompanied by producing, at any one time, a greater number of eggs per given body weight than does *C. bicolor*.

A SURVEY OF GENETIC CHANGES AND SEARCH FOR SEX-SPECIFIC MARKERS BY AFLP AND SAMPL IN A BREEDING PROGRAM OF CHINESE SHRIMP (*PENAEUS CHINENSIS*)

LIUSUO ZHANG,¹ XIAOYU KONG,¹ ZINIU YU,^{1*} JIE KONG,² AND LIMEI CHEN¹

¹The Key Laboratory of Mariculture of Ministry of Education, Ocean University of China, Qingdao 266003, People's Republic of China and ²Yellow Sea Institute of Fisheries Research, Chinese Academy of Fisheries Science, Qingdao 266071, People's Republic of China

ABSTRACT Amplified fragment length polymorphism (AFLP) and selective amplified microsatellite polymorphic loci (SAMPL) were used for a survey of genetic changes over three generations and search for sex-specific markers in a breeding program of Chinese shrimp *Penaeus chinensis*. For genetic survey, a total of 247 and 140 clearly defined bands from 6 AFLP and 4 SAMPL primer sets, respectively, were generated. Both estimated percentage of polymorphic loci (ranging from 41.3% to 47.8%) and average gene diversity (ranging from 0.168 to 0.190) were not significantly different from each other among generation samples, suggesting no significant change at level of genetic variation by AFLP and SAMPL analysis. Despite the frequency change of band-presence allele at all loci over generations showed no clear and traceable patterns, the values of genetic distances and identities between founder stock and sequential generations reflected the accumulation of genetic changes over generations, probably due to isolation and selection. Analysis of molecular variance (AMOVA) and pairwise Φ_{PT} statistics of AFLP and SAMPL data indicated that significant genetic variation was distributed among generation samples ($P < 0.01$). The use of more variable markers may help further examination of genetic change over generations in more details. Search for sex-specific markers with AFLP and SAMPL loci in this study failed to detect any putative markers, despite 2,110 bands in total were generated through extensive screening with 25 AFLP and 16 SAMPL primer pairs. The inability in detection of sex-specific markers may be due to any of several reasons such as weak correlation between the genotypic and phenotypic sex, high genetic diversity in sex-related regions, or just lack of enough number of loci for screening.

KEY WORDS: shrimp, *Penaeus chinensis*, AFLP, SAMPL, genetic changes, sex-specific markers

INTRODUCTION

The Chinese shrimp, *Penaeus chinensis*, has been an important species for the shrimp fishery for many decades in China (Yu & Chan 1986). Its aquaculture has developed rapidly since the success of artificial propagation in early 1980s and the production reached 200,000 tons per year in the early 1990s (Wang et al. 1997). Unfortunately, the extensive outbreaks of shrimp diseases (mainly white spot syndrome virus, WSSV) in 1993, and the following few years resulted in significant decline in production in those intensive production areas. The development of disease-resistant strains of Chinese shrimp represents a major task for the scientific and aquaculture community.

A selection program aimed to develop disease resistance (mainly to WSSV) strains was initiated in 1998, and mass selection has been conducted for three generations (a higher survival rate than that in control was observed). For a breeding program, it is usually important that not only the phenotypic performance of the selected strain be closely checked, but also genetic changes over generations be monitored carefully. A major concern for selected populations is possible loss of genetic variability and inbreeding (Allendorf & Ryman 1987, Hedgecock & Sly 1990, Hedgecock et al. 1992, Gaffney et al. 1992). Loss of genetic variation reduces response to selection and severe inbreeding may lead to poor survival and slow growth (Virjenhoek et al. 1990, Launey & Hedgecock 2001).

Shrimp still remains among the list of aquatic animals in which little is known about sex differentiation and determination. Although significant difference in growth rate exists between female and male, as with many other species, no sex chromosomes has

been detected yet (Xiang et al. 1993), and no sex-specific genetic marker has been reported in *P. chinensis*.

Advances in molecular biology have provided various polymorphism techniques for study of genetic variation and search for genetic markers linked to specific traits. Amplified fragment length polymorphism (AFLP, Vos et al. 1995) is a popular polymorphism system that combines the advantages of RFLP and PCR, with no requirement of prior sequence characterization of the target genome. The number of polymorphisms detected and the level of fingerprint reproducibility per reaction is much higher than that revealed by most of the other PCR-based methods because of its simultaneous coverage of many loci in a single assay. Selective amplified microsatellite polymorphic loci (SAMPL) analysis (Witensboer et al. 1997) is a modification of AFLP methodology, which utilizes the same template DNA as that of AFLP. However, the selective amplification uses one of the AFLP primers in combination with a specially designed SAMPL primer. The SAMPL primer essentially comprises of a compound microsatellite sequence, and such a SAMPL primer design ensures preferential amplification of microsatellite-like sequences.

In this study, AFLP and SAMPL have been used for analyzing genetic changes over generations of a selected strain of *P. chinensis*. At the same time, a search for sex-specific markers was conducted for potential identification of markers associated with sex differentiation and determination, using these two marker systems.

MATERIALS AND METHODS

Sample Collection and DNA Isolation

Thirty-six individuals representing four generations sample (9 from each generation randomly) were obtained from Yellow Sea Institute of Fisheries Research, Chinese Academy of Fisheries Sci-

*Corresponding author. E-mail: carlzyu@ouc.edu.cn

ences. Four generations were designated as G_0 , G_1 , G_2 , and G_3 , respectively. G_0 sample was the founder stock for selection, which was the progeny of several hundreds of wild shrimp captured in Weihai waters, the Yellow Sea, China. Mass selection was conducted with disease challenge for 3 generations (G_1 through G_3). Briefly, about 200 mature females and males (roughly equal number of each sex) from G_0 were used to reproduce in a local hatchery. These females with an attached spermatophore were separated for egg release and fertilization to build the next generation (G_1). Juvenile shrimp were grown in local shrimp ponds until maturation. One year later, about the same number of females and males were selected from G_1 and mated to establish G_2 in the same hatchery. The same work was repeated for the establishment of the G_3 population.

Genomic DNA was extracted from muscle using the method described by Aljanabi and Martinez (1997). DNA samples were checked by agarose gel electrophoresis, and their concentrations were determined with Beckman-spectrophotometer (Model DU 520, Beckman). For search of sex-specific markers, two separate pools consisting of DNAs from four females and five males, respectively, were used to minimize possible effects of individual variation and improve efficiency of screening process.

AFLP Analysis

AFLP procedure was performed as described by Vos et al. (1995). Genomic DNAs were digested with *EcoRI* and *MseI*, and ligated with relevant adaptors overnight at room temperature. Pre-selective amplification was performed using primers with one selective base at their 3' end (E-A and M-C). For genetic survey, 6 pairs of selective primers, each containing 3 selective nucleotides at their 3' end, were used for selective PCR. The 6 selective primer pairs were E-AAG/M-CCT, E-AAG/M-CTG, E-AAG/M-CAC, E-AAG/M-CGA, E-ACG/M-CTC, and E-ACG/M-CCT, respectively. For the search of sex-specific markers, 25 AFLP (5 *EcoRI* primers \times 5 *MseI* primers) primer pairs were used. The 5 *EcoRI* primers included E-AAC, AAG, ACA, ACC, and ACG, and 5 *MseI* primers were M-CAC, CCT, CGA, CTC, and CTG, respectively.

With the addition of an equal volume of sequencing dye (98% formamide, 10 mM EDTA, 0.025% xylene cyanol, 0.025% bromophenol blue), PCR products obtained in the selective reaction were denatured at 95 °C for 5 min, and then immediately cooled on ice for at least 5 min. A 2.5 μ L of each sample was loaded on a denaturing polyacrylamide (6%) gel and run at 60 W. After silver staining (Bassam et al. 1991), bands were visualized under white-illumination. The developed gels were dried at room temperature for 24 h before scoring the bands.

SAMPL Analysis

SAMPL procedures used here were the same as that of AFLP, described earlier in the section of AFLP Analysis, except that SAMPL primers replaced *MseI* primers in the selective amplifications (Witsenboer et al. 1997). For genetic survey, 4 selective primer pairs were used, which included E-AAG/SAM01, E-AAG/SAM02, E-ACG/SAM01, and E-ACG/SAM02, respectively (Table 1). For the search of sex-specific markers, 16 (3 *EcoRI* and 1 *MseI* primers \times 4 SAMPL primers) primer pairs were used. They were E-AAC, AAG, ACG and M-CGA, and 4 SAMPL primers, respectively (see Table 1).

TABLE 1.

K = G or C; R = A or G; Y = C or T; H = A or C or T; V = A or C or G.

Data Analysis

AFLP and SAMPL profiles were scored manually as "1"s (band presence) or "0"s (band absence). Two assumptions were made: (1) bands come from independent nuclear loci and do not migrate to the same position on gel; and (2) each band represents a dominant genotype at a locus, where lack of the same band in another individual correspond to the alternative homozygous recessive genotype in the Hardy-Weinberg equilibrium (Lynch & Milligan 1994).

The unbiased estimator of Lynch and Milligan (1994) was used to estimate frequency of two alleles (1 and 0) at each locus and expected heterozygosity with combined AFLP and SAMPL data was calculated accordingly. Pairwise genetic distances and genetic identities were calculated with two data sets jointly using POPGENE (Yeh et al. 1999). AMOVA and pairwise Φ_{PT} statistics of AFLP and SAMPL data were conducted to determine genetic difference of the generations with GenAlEx V5 (Peakall & Smouse 2001).

RESULTS

In genetic survey, six AFLP primer combinations and four SAMPL primer pairs generated 247 and 140 clearly defined bands, respectively, averaging 41.2 bands per primer pair for AFLP and 35.0 bands for SAMPL. Most amplified profiles were highly specific and reproducible, and ambiguous bands were excluded from further analysis. The size of most scored bands ranged from 100 to 400 bp. The percentage of polymorphic loci and average gene diversity (Nei et al. 1975) with combined AFLP and SAMPL data ranged from 41.3 to 47.8% and from 0.168 to 0.190, respectively (Table 2), which were not significantly different from each other (Chi-test, $P = 0.56$ and 0.99 , respectively), suggesting no significant change in the level of genetic variation by AFLP and SAMPL. The frequency change of band-presence allele at all loci over generations showed no clear and traceable patterns.

The genetic distances and genetic identities with combined data sets among generations are shown in Table 3. Clearly, the values of distances or identities between G_0 and other generations increased or decreased over successive order accordingly, reflecting the accumulation of genetic changes over generations. AMOVA

TABLE 2.
Average percentage of polymorphic loci and Nei's (1973) gene diversity with combined AFLP and SAMPL data.

	G_0	G_1	G_2	G_3
Percentage of polymorphic loci	41.3	45.7	43.4	47.8
Nei's gene diversity	0.168	0.183	0.173	0.190

TABLE 3.

Nei's (1978) genetic distances (below diagonal) and genetic identities (above diagonal) among generations with joint AFLP and SAMPL data.

	G ₀	G ₁	G ₂	G ₃
G ₀	—	0.9187	0.8797	0.8652
G ₁	0.0848	—	0.9415	0.9161
G ₂	0.1282	0.0603	—	0.9294
G ₃	0.1448	0.0876	0.0732	—

results from both data sets showed that significant genetic variation was distributed among generation samples ($P < 0.01$), with percentages of total variance of 17% and 26%, respectively, among generations for AFLP and SAMPL data (Table 4). Furthermore, pairwise Φ_{PT} statistics in both data sets indicate that significant genetic difference occurred between any neighbor generation pair and increased over sequential generation order (Table 5).

With respect to the search of sex-specific marker, 2,110 bands in total were generated with AFLP and SAMPL, but unfortunately, analysis and comparison showed that no putative sex-specific band was identified for both sexes in the two marker systems.

DISCUSSION

Genetic Changes over Generations

While AFLP has been extensively used in the studies of genetic diversity of populations, germplasms, cultivars, and strains for plants, it has recently been applied to similar researches in aquatic animals (Seki et al. 1999, Moore et al. 1999, Miller et al. 2000, David et al. 2001). AFLP is considered very efficient at revealing genetic difference due to its ability to screen polymorphism on genome scale despite lower average heterozygosity (Vos et al. 1995, Maguire et al. 2002). SAMPL is a novel approach that emerged recently for genetic studies and shown useful in plants. Although based on small sample sizes, the similar estimation of average percentage of polymorphic loci and gene diversity of four samples indicated that no significant change at level of genetic variation was observed among generations by AFLP and SAMPL analysis. This maintenance of genetic variation level is likely due to the large size of founder population and the reproduction populations used in the following generations. It could help reduce the adverse effects of genetic drift, selection, and inbreeding that may occur in a breeding program. This result should be contributed by the fact that AFLP's advantage of comprehensive evaluation of multi polymorphic loci on genome range compensated the effect of

TABLE 4.

Analysis of molecular variance of AFLP and SAMPL in 4 generations.

Data	Source of Variation	df	Variance	Φ		
				% Total	Statistics	P Value
AFLP	Among generations	3	4.66	17	0.165	0.001
	Within generations	32	23.54	83		
SAMPL	Among generations	3	3.85	26	0.260	0.001
	Within generations	32	10.96	74		

the small sample size. With AFLP, Seki et al. (1999) detected significant and clear genetic difference among three Ayu *Plecoglossus altivelis* populations (8 fish per sample) by using 19 primer combinations; and significant difference in average heterozygosity for three samples were also found. Similarly, it was confirmed that multilocus RAPD (6 random primers) detected very similar molecular differentiation among blacklip abalone *Haliotis rubra* populations in small sample size (10 animals per sample) as revealed by microsatellites (Huang et al. 2000).

Usually, heterozygosity level and allele diversity shift are considered as indicators for genetic changes of populations under selection or culture. Shordoni et al. (1986) examined genetic diversity with 20 allozyme loci for sequential hatchery generations in *P. japonicus*, noticing progressive reduction of heterozygosity from 0.102 down to 0.039 in samples from generation F₁ through F₆. However, Cruz et al. (2004) found that high heterozygosities (in 2 microsatellite loci) were still maintained through two generations of the Pacific white shrimp *Litopenaeus vannamei* under selection. Nevertheless, three studies of penaeids species have reported lower numbers of alleles at microsatellite loci in cultured populations than in wild or founder stocks (Wolfus et al. 1997, Bierne et al. 2000, Xu et al. 2001). In molluscan, similarly, several studies showed that no association was observed between selection or culture and loss of heterozygosity in the Pacific oyster *Crassostrea gigas* (Hedgecock & Sly 1990), hard clam *Mercenaria mercenaria* (Dillon & Manzi 1987) and American oyster *C. virginica* (Vrijenhoek et al. 1990, Yu & Guo 2004). However, the reduction of allele number in these selected populations was commonly observed (Dillon & Manzi 1987, Vrijenhoek et al. 1990, Yu & Guo 2004). Obviously, loss of genetic variation resulted from genetic drift, bottlenecks, selection, and inbreeding caused by a reduced effective population size.

Despite no significant change in the level of genetic variation was observed through AFLP and SAMPL analysis, it is risky to say that no significant change at level of genetic variation occurred at all. Because allele diversity change, which is another indicator of genetic changes, could not be detected via these two methods. From the literature mentioned above, one can see that the two indicators do not match in many cases. Therefore, for more details of genetic change over generations, further studies using microsatellite or allozyme markers will be helpful and necessary. Recently, some microsatellites have been developed for Chinese shrimp (Liu et al. 2004) and could be used for further analysis of this breeding program.

Because isolation and selection of stocks may lead to deterioration via inbreeding and reduction of effective population size, genetic changes should be monitored carefully following operation of selection. Despite complicated frequency change of band-presence allele and unavailability of traceable patterns of polymorphic loci over generations in this study, AFLP and SAMPL

TABLE 5.

Pairwise Φ_{PT} statistics of AFLP (below diagonal) and SAMPL (above diagonal) in generations. P value in parenthesis.

	G ₀	G ₁	G ₂	G ₃
G ₀	—	0.281 (0.001)	0.406 (0.001)	0.410 (0.001)
G ₁	0.118 (0.001)	—	0.066 (0.067)	0.182 (0.002)
G ₂	0.202 (0.001)	0.106 (0.011)	—	0.135 (0.005)
G ₃	0.257 (0.001)	0.177 (0.005)	0.106 (0.005)	—

did screen out occurrence of difference over generation samples. As indicated by genetic distances, identities and result of AMOVA, isolation and selection caused the accumulation of genetic changes over sequential generations.

From AMOVA of SAMPL data, it was noted that estimation of percentage of total variance distributed among generations was higher than that in AFLP data (26% vs. 17%), so was from pairwise Φ_{PT} statistics of SAMPL. This difference was very likely due to the characters of polymorphism from SAMPL. Theoretically, SAMPL screens 4 types of polymorphisms: (1) codominant microsatellite polymorphisms, which resulted from the number variation of repeat units within microsatellites targeted by the microsatellite-anchor primers; (2) presence/absence-style polymorphisms arising from variation of the annealing sites for the microsatellite-anchor primer; (3) codominant polymorphisms originating from insertion/deletions in amplified fragments; and (4) presence/absence-style polymorphisms originating from variation in restriction sites (Yang et al. 2001). Whereas type 2 and 4 could be detected as dominant polymorphism, type 1 and 3 may cause incorrect scoring information due to their codominant nature, and then magnified the difference among samples involved to some extent. In addition, another reason responsible for this difference could be the smaller data size (140 bands) in SAMPL than that in AFLP (247 bands).

Search for Sex-specific Markers

Understanding the mechanism of sex determination and differentiation is important for study of shrimp biology and aquaculture practices. Although recently Li et al. (2003) mapped sex-linked markers on the maternal linkage map in Kuruma prawn *P. japonicus* and implied that the female may be the heterogametic sex in this species, search for sex-specific markers with AFLP and SAMPL loci in current study has failed to detect any putative

markers, despite extensive screening with 25 AFLP and 16 SAMPL primer pairs (2,110 bands in total were generated). Previously, attempts to detect sex-specific markers in Atlantic salmon (*Salmo salar*) and green spotted pufferfish (*Tetraodon nigroviridis*) with RAPD, AFLP, and RDA (representational difference analysis) were made, but were not successful (McGowan & Davidson 1998, Li et al. 2002). Sex determination in crustacean has been studied for the last 2 decades (Malecha 1983, Legrand et al. 1987, Benzie 1998, Hulata 2001), with the exception of decapods. Lack of sex chromosome differentiation in penaeids has been observed, and no environmental factors of sex determination have ever been reported (Korpelainen 1990). As mentioned earlier, karyotype analysis detected no dimorphic pair of chromosomes, and it may imply absence of sex chromosomes or their weak differentiation in *P. chinensis* genome. The inability to detect of sex-specific markers in this kind of limited search could be due to any of the following reasons: very weak correlation between the genotypic and phenotypic sex due to modifiers, high genetic diversity in sex-related regions on genome among the individuals studied, or biallelic and autosomal nature of sex-determining genes (Li et al. 2002, McGowan & Davidson 1998). Of course, it could not be ruled out that the number of loci used in this search may not be enough to screen out the sex-specific markers, if there is any. More work is needed before we come to any conclusion.

ACKNOWLEDGMENTS

The authors thank Mr. B.W. Liu and D. R. Hu for their assistance with DNA extraction and Mr. Sean Boyd for English review. This work was supported by an 863 project of Ministry of Science and Technology of China (2001AA620105) and funded by the Key Laboratory of Mariculture of Ministry of Education, Ocean University of China.

ABSTRACT This study presents data on the effect of temperature and fluctuations in salinity on the oxygen consumption, nitrogen excretion, and osmoregulation of *Litopenaeus stylirostris* juveniles to determine the combinations, so these can be used to optimize the culture conditions. The oxygen consumption rate of juveniles acclimated to 23°C, 28°C, and 33°C was measured. Fluctuating salinity levels were applied to these organisms in a sequence of 40‰, 32‰, 25‰, 16‰, 25‰, 32‰, and back to 40‰. The results indicate that metabolic rate of blue shrimp exposed to salinity fluctuation was not affected significantly. When the salinity was reduced from 40‰ to 25‰ the ammonium excretion of the shrimp was increased, in a 16‰ salinity in all temperatures the ammonium production increased in average of 220%, when the salinity was increased from 16‰ to 40‰ the ammonium excretion of the shrimp was reduced. Hemolymph osmolarity of the organisms was hyposmotic as the salinity was reduced from 40‰ to 33‰, hyperosmotic during the 25‰ to 16‰ interval and hyposmotic as the salinity increased from 25‰ to 40‰. The isosmotic points had an interval of 676.8–700.7 mmol Kg⁻¹ (23.7‰ to 24.6‰). The excretion rate of ammonium of the shrimp acclimated at temperatures of 23°C, 28°C, and 33°C was related with the pattern of osmoregulation, when the shrimp were hyper-regulators, ammonium increased and diminished when they were hypo-regulators. To optimize the culture of *L. stylirostris* in controlled conditions, we propose that they be cultivated in salinities of 25‰ and temperatures of 28°C because these are considered the optimal conditions, also this environment is free of stress, and for this reason the growth of shrimp is increased.

KEY WORDS: shrimp, temperature, salinity fluctuation, oxygen consumption, ammonium excretion, osmoregulation, *Litopenaeus stylirostris*

INTRODUCTION

Temperature and salinity of the water are among the most important environmental factors that affect the life of the penaeids shrimp (Chen & Nan 1995). The adaptative capacity of the penaeids is specific and determined by a number of factors, that have caused shrimp species to be distributed differently in the marine-estuarine gradient (Claybrook 1983). In recent years the studies on the physiology of the penaeids have increased, due to interest in the aquacultural practice with these organisms; through these investigations optimal conditions for their cultivation can be delimited (Brito et al. 2000).

One of the physiologic responses that can be correlated with the changes of the environmental parameters is the oxygen consumption rate, because it is related with the metabolic work and energy flow that the organisms must destine for the mechanisms of homeostatic control (Salvato et al. 2001). Therefore the measurement of the oxygen consumption in the aquatic animals is a valid method to evaluate the effect of environmental factors such as temperature, salinity, exposition to pollutants, light intensity, and the dissolved oxygen, because it allows the determination of the energetic cost associated with the physiologic stress that these combinations impose on the organisms (Kinne 1970, Villarreal & Rivera 1993, Brown & Terwilliger 1999, Lemos et al. 2001, Altinok & Grizzle 2003).

The ammonium excretion rate has been used to evaluate the effect of various environmental factors on the physiology of the crustaceans (Jiang et al. 2000). The ammonium represents 40% to 90% of the total nitrogen excreted by the crustaceans and is con-

tinuously released through the branchial epithelium (Hartenstein 1970, Kinne 1977, Regnault 1987). A decrease of the environmental osmotic concentration gives a result of a decrease on the amino acids in the tissues and an increase in the ammonium excretion on the organisms (Lange 1972). Significant effects of temperature and salinity on ammonium excretion have been quantified in some species of crustaceans of commercial importance as in *Macrobrachium rosenbergii*, De Man (Nelson et al. 1977, Stern et al. 1984, Díaz Herrera & Buckle Ramirez 1993); *Farfantepenaeus indicus*, Milne-Edwards (Gerhardt 1980); *F. chinensis*, Osbeck (Chen & Lin 1992, 1995); *Marsupenaeus japonicus*, Bate (Chen & Lai 1993); *Penaeus monodon*, Fabricius (Chen et al. 1994); *Farfantepenaeus aztecus*, Ives (Hernández & Díaz 1995); and *Litopenaeus vannamei*, Boone (Jiang et al. 2000, Díaz et al. 2001).

The environmental variation of the salinity disorganizes the osmotic balance in the penaeids, provoking the readjustment of the osmotic concentration of the hemolymph on these organisms. The ability for osmoregulation in decapods was evaluated by Charmanier et al. (1988, 1989) through the osmoregulatory capacity (OC), defined as the difference between the osmolality of the hemolymph and the external medium osmolality for a given salinity. The OC is a useful tool to evaluate the physiologic condition of the shrimps as well as to detect the sublethal effects of the stress in the culture systems (Lignot et al. 2000).

During the last 4 decades, the osmoregulatory physiology of different species of penaeids has been studied to evaluate the optimal conditions for their culture as in: *Farfantepenaeus aztecus* (Bishop et al. 1980, Castille & Lawrence 1981, Howe et al. 1982, Hernández & Díaz 1995); in *Litopenaeus setiferus*, Linnaeus *L. stylirostris* Stimpson and *L. vannamei* (Williams 1960, Castille & Lawrence 1981, Rodríguez 1981); in *P. esculentus*, Haswell; *Fen-*

*Corresponding author. E-mail: fdiaz@cicese.mx

neropenaeus merguensis, De Man; and *Metapenaeus bennettiae* Racek and Dall (Dall 1981); in *F. indicus* (Parado-Esteva et al. 1987); in *P. monodon* (Cawthorne et al. 1983, Ferraris et al. 1986); in *Marsupenaeus japonicus* (Charmantier-Daures et al. 1989); in *Fenneropenaeus chinensis* (Chen & Lin 1994, Chen et al. 1995, Chen & Lin 1998); and *P. semisulcatus*, De Hann (Clark 1992). However, the osmoregulation processes in these organisms were studied in regimes of constant salinity, whereas in the lagoon-estuarine systems in which these crustaceans normally inhabit, the factors are unstable and present marked variations in temperature, salinity, and dissolved oxygen throughout the year (Salvato et al. 2001).

The blue shrimp *Litopenaeus stylirostris* is distributed from Punta Abreojos, Baja California down to Tumbes, Peru. This species is commercially cultivated in Ecuador and México, inhabits lagoons, estuaries and bays, places with a varying hydrography through the year, affecting organisms that inhabit in these aquatic systems, due to well defined periods of rain and drought (low water) (Rodríguez 1981, Aragón 2000). The aquacultural potential that the blue shrimp *L. stylirostris* has in México makes it necessary to know the effect of the variations of temperature and salinity on the oxygen consumption, nitrogen excretion and the osmoregulatory capacity, to determine the adequate environmental conditions to optimize its cultivation.

MATERIALS AND METHODS

A number of *Litopenaeus stylirostris* juveniles ($n = 1500$) was acquired in the production farm "Camarón Dorado S.A." located in Huatabampo, Sonora, México. The organisms were placed on three reservoirs of 2000 l in the laboratory with continuous flow of seawater and constant aeration. They were maintained at a temperature of $28^{\circ}\text{C} \pm 1^{\circ}\text{C}$ and a salinity of 35‰ during a week. The shrimps ($n = 900$) with a wet weight of 2.8 to 5.0 g were transferred to three circular reservoirs of 500 l for acclimation during 30 days to the temperatures of 23°C , 28°C , and $33^{\circ}\text{C} \pm 1^{\circ}\text{C}$ and 35‰ salinity. The temperatures of 23°C and 33°C were obtained by decreasing or increasing the temperature of the water of the reservoirs at a rate of 2°C by day. During this phase the shrimps were fed twice a day with Rangen diet for shrimp with 35% of protein. Once the period of thermal acclimation was over, salinity was increased to $40\text{‰} \pm 1\text{‰}$ and remained in these conditions for 6 days, sufficient time for the shrimps to stabilize their internal medium (Bishop et al. 1980, Rosas et al. 2001).

Of each experimental condition, 20 organisms in intermoult stage were selected. The stage of the moult cycle was identified according to the procedure described by Huner and Colvin (1979), 12 h before initiating the measurements they were introduced individually in a semi-opened respirometer as described by Díaz et al. (1989) which consists of 21 respirometric chambers of 1 l. These organisms, as well as the remainders ($n = 140$) that stayed in the reservoirs, were exposed during 4 h in a cycle of 28 h simulating a natural variation similar to an estuarine system, to the effect of the salinity fluctuation as the salinities were changed in sequence to 40‰, 32‰, 25‰, 16‰, 25‰, 32‰, and 40‰, according to the methodology described by Vanegas et al. (1988). To obtain the salinities lower than 35‰ dilutions were carried out using freshwater and the salinity of 40‰ was obtained by the addition of Instant Ocean salts. The shrimps were not fed 24 h before beginning the determination of oxygen consumption, ammonium excretion, and osmoregulatory capacity.

The measurements of oxygen consumption and ammonium excretion were quantified simultaneously in 20 organisms placed in the respirometric chambers, the water flow on the chambers remained open for 3 hours to let the adjustment of the internal medium of the organisms exposed to a change of salinity (Díaz et al. 2001). Before closing the flow, two water samples were taken to measure the initial oxygen and ammonium concentration. Subsequently the chambers remained closed for 1 hour to avoid a reduction of the dissolved oxygen of 25% to 30%, and this constituted a stress factor (Stern et al. 1984). Before the water flow was re-established in the chambers, two water samples were taken to measure the final dissolved oxygen and ammonium production.

The dissolved oxygen concentration in the water samples were measured with a dissolved oxygen meter YSI, model 52, provided with a polarographic sensor, which was inside of an acrylic hermetic chamber with a 10-mL capacity with adequate stirring. The rate of oxygen consumption of the shrimps was calculated as the difference between the initial and the final concentrations and it was expressed as $\text{mg O}_2 \text{ h}^{-1} \text{ g}^{-1}$ of dry weight (d.w.) calibration in air at 100% relative humidity, to achieve this field probes can be placed in the plastic calibration bottle with a moistened sponge. For the quantification of ammonium excretion we used the phenolhypochlorite method (Rodier 1979). The ammonium production of the shrimps in each experimental condition was calculated as the difference between the final concentration and the initial and is expressed in $\text{mg NH}_4^+ \text{ h}^{-1} \text{ g}^{-1}$ d.w. The 21st chamber was used as a control to measure the oxygen consumption and the ammonium production by the microorganisms and to make the necessary corrections.

The determination of the osmotic pressure was carried out in the shrimps that remained in the reservoirs and they were exposed to the same regimen of salinity fluctuation. Before the salinity changed, 20 shrimps of the reservoir were extracted at random. To each organism a single hemolymph sample of 10 μL was extracted with an automatic pipette directly off the thoraco-abdominal membrane (previously dried with absorbent paper). Osmolality of the hemolymph and the external medium were measured with a Wescor 5520 vapor osmometer, calibration was run a 290 mmol/kg standard and 1000 mmol/kg standard to establish baseline calibration for these standards, and the data were expressed in mmol Kg^{-1} . The linear relationship in the decreased or increased salinity and osmolality at different temperatures were tested using linear regression (Sigma-Stat). The isosmotic points (where hemolymph osmolality is equal to medium osmolality) were determined using the formula of Ferraris et al. (1986). The osmoregulatory capacity (OC), in the blue shrimp was calculated according to Lignot et al. (2000) as the difference between the hemolymph osmolality and the medium osmolality.

Immediately after ending the experiments the shrimps were killed by immersion in boiling water, dried overnight at 60°C , placed on a desiccator for 2 hours and weighed on a balance (OHAUS Explorer) to determine the d.w.

The data of the oxygen consumption and ammonium excretion of the shrimps exposed to the different experimental conditions were plotted in parallel boxes (Tukey 1977). Within the boxes 50% of the data were distributed in the median and the confidence intervals, the other 50% remained distributed in each bar. A 2-way analysis of variance was used as previous determination of the normality and homoscedasticity of the data (Sigma-Stat), to determine the effect of the temperature and salinity fluctuation on the

oxygen consumption, nitrogen excretion and the hemolymph osmotic pressure of *L. stylirostris*.

RESULTS

The oxygen consumption rate in *Litopenaeus stylirostris* juveniles exposed to fluctuations of salinity and maintained in 23°C was 1.1–1.51 mg O₂ h⁻¹ g⁻¹ d.w. This rate was of 1.70–1.98 mg O₂ h⁻¹ g⁻¹ d.w. in organisms acclimated to 28°C and it increased 230% in comparison with those exposed to 33°C (Fig. 1). An analysis of variance indicated that temperature had a significant effect ($P < 0.05$) on the oxygen consumption of the blue shrimp, but the effect of salinity and the interaction temperature-salinity was not significant ($P > 0.05$).

L. stylirostris juveniles exposed to salinity of 40‰ and acclimated to 23°C and 28°C the lower ammonium excretion rate of 0.04–0.08 mg NH₄⁺ h⁻¹ g⁻¹ d.w. was obtained. In the shrimps maintained in 33°C the excretion rate increased significantly up to 0.18 to 0.35 mg NH₄⁺ h⁻¹ g⁻¹ d.w. When the organisms were exposed to descending salinities of 40‰ to 25‰, ammonium excretion increased. In salinity of 16‰ and in the three temperatures in which the shrimps were maintained, the ammonium production increased an average of 220%. When the organisms were exposed to ascending salinities, the excretion of the shrimps was reduced significantly ($P < 0.05$) (Fig. 2). An analysis of variance indicated that there was a significant effect of temperature and salinity on the ammonium excretion rate of *L. stylirostris* ($P < 0.05$), the interaction between temperature and salinity was not significant ($P > 0.05$).

Hemolymph osmolarity of *L. stylirostris* acclimated to 23°C, 28°C, and 33°C and exposure to salinity fluctuation was related linearly; the obtained slopes had an interval of 0.113 to 0.264 (Table 1). When salinity was reduced from 40‰ to 33‰ (1,278–965 mmol Kg⁻¹) the hemolymph concentration was hypo-osmotic with an interval of 873–777 mmol Kg⁻¹ in respect of the external medium. In the interval of salinities of 25‰ to 16‰ (752–556 mmol Kg⁻¹) the hemolymph of the shrimps was hyperosmotic with an interval of 677–770 mmol Kg⁻¹. When the salinity was increased from 25‰ to 40‰ the osmolality of the internal medium of the shrimps was hypo-osmotic with an interval of 737–848 mmol Kg⁻¹ (Fig. 3). An analysis of variance indicated that the fluctuation of salinity had a significant effect ($P < 0.05$) on the hemolymph concentration of the shrimps; the temperature and the interaction between temperature and salinity did not have a significant effect ($P > 0.05$).

The acclimation temperature did not affect significantly ($P > 0.01$) the values of the isosmotic points of the organisms exposed to salinity fluctuation. The isosmotic points obtained in the shrimps exposed to salinity fluctuation had an interval of 726–758 mmol Kg⁻¹ (24.9–25.9‰), when the increased salinity had an interval of 751–766 mmol Kg⁻¹ (25.7–26.2‰) (Fig. 3).

The osmoregulatory capacity (OC) in juveniles of the blue shrimp was modified significantly by salinity ($P < 0.05$) the hemolymph was hypo to hyper-osmotic since in the salinities of (40‰, 32‰, 40‰) had an interval of -417 to -167, whereas the salinities of (25‰, 16‰, 25‰) increased from 18‰ to 143‰ (Fig. 4). The temperature did not affect significantly ($P > 0.05$) the osmoregulatory capacity of the organisms.

DISCUSSION

The respiratory rate in the crustaceans is modified by external factors as salinity, light intensity, dissolved oxygen and tempera-

ture (Kutty et al. 1971, Bishop et al. 1980, Dalla-Via 1986, Kurmaly et al. 1989, Martínez-Palacios et al. 1996). In *Litopenaeus stylirostris* juveniles a direct relationship was obtained between the oxygen consumption rate and temperature. This same response was obtained by Kutty et al. (1971) in *Fenneropenaeus indicus*, in *Penaeus monodon* by Kurmaly et al. (1989) and Chen and Lai (1993), in *Farfantepenaeus californiensis* (Holmes) by Villarreal and Ocampo (1993), and Martínez-Palacios et al. (1996) in *Litopenaeus vannamei*. It has been emphasized by Venkataramiah et al. (1974) that the respiratory rate cannot be considered as a good index of the salinity tolerance, except in the cases where the experimental temperature correspond to the natural characteristics of the habitat of the organisms. For blue shrimp a temperature of 28°C corroborates the above-mentioned fact because it corresponds to the preferred temperature determined for this species by Re et al. (2000). Furthermore it is within the average interval experienced in their natural environment.

The oxygen consumption of *L. stylirostris* exposed to salinity fluctuation was not affected significantly. In other euryhaline decapods salinity was not found to significantly affect the oxygen consumption if the experimental organisms were acclimated to the test salinities and if this were not extreme (Bishop et al. 1980, Gaudy & Sloane 1981, Díaz-Herrera et al. 1992, Villarreal & Rivera 1993, Villarreal et al. 1994, Salvato et al. 2001). In aquatic organisms that have been acclimated to a new salinity, Kinne (1967) described four types of metabolic response. The blue shrimp exposed to salinity fluctuation exhibited the type I response because the oxygen consumption was not modified significantly. According to Newell (1976) physiologic rate independence from salinity obtained for blue shrimp is a characteristic of animals that experience highly variable environmental conditions. For other osmoregulator decapods it has been demonstrated, that salinity did not have a pronounced effect on the oxygen consumption if the experimental organisms were acclimated to salinities and if these are not extreme (Bishop et al. 1980, Gaudy & Sloan 1981, Villarreal & Rivera 1993, Salvato et al. 2001). Acclimation time for the *Litopenaeus stylirostris* juveniles to each condition of salinity was sufficient to stabilize their internal medium (Díaz et al. 2001). Furthermore, the intervals of the used salinities correspond to the natural variations to which this species is exposed (Aragón 2000).

In the juveniles exposed to salinity fluctuation ammonium excretion rate was increased, when salinity was reduced from 40‰ to 16‰. This response is related to an increase in the catabolism of the amino acids, because: according to Chen (1998) the shrimps in the lower salinities use proteins as the primary source for requirements of energy. This response has been reported in penaeids such as *M. japonicus*, *F. chinensis*, *P. monodon*, *F. aztecus*, and *L. vannamei* (Spaargaren et al. 1982, Chen & Lin 1992, Chen & Lai

Figure 3. Relation between hemolymph osmolarity of *Litopenaeus stylirostris* and medium osmolarity when they were exposed to combinations of temperature and fluctuating salinities.

1993, Chen et al. 1994, Hernández & Díaz 1995, Jiang et al. 2000, Díaz et al. 2001).

In the blue shrimp exposed to salinity fluctuations, the ammonium excretion rate was related to the processes of osmoregulation, because excretion increased when the shrimps were hyper-regulators and reduced when they were hypo-regulators. It has been demonstrated that there is an increase in the active incorporation of Na⁺ followed by the transfer from the organisms to dilute mediums, and this was related to an increase in ammonium excre-

tion because the sodium absorption is required to compensate the lost, caused by the operation of the exchange pump Na⁺/NH₄⁺ (Mangum et al. 1976, Pressley et al. 1981). To balance the osmotic concentration of the hemolymph when exposed to dilute mediums, the shrimps use these mechanisms. The quantification of nitrogen excretion rate in the shrimps exposed to the effect of different environmental factors is an important requirement for the design and operation of the intensive production systems (Jiang et al. 2000).

In the *L. stylirostris* juveniles, the osmoregulation pattern obtained was typical of many crustaceans that inhabit the lagoon-estuarine systems. They were hypoosmoregulators and hyperosmoregulators above and below the isosmotic point (Vernberg & Vernberg 1972, Mantel & Farmer 1983). The isosmotic points for the juveniles of the blue shrimp acclimated to different temperatures and exposed to salinity fluctuations had an interval of 726–766 mmol Kg⁻¹ (24.9‰ to 26.2‰). These values are within the interval of isosmotic points reported by Brito et al. (2000) and Díaz et al. (2001) in 8 and 11 different species of penaeid respectively. Lemaire et al. (2002) reported an isosmotic point 735 mmol Kg⁻¹ for juvenile shrimp *L. stylirostris* maintained in constant salinities. In the *L. vannamei* juveniles exposed to salinity fluctuations and acclimated to different temperatures, Díaz et al. (2001) obtained that the isosmotic points had an interval of 712–777 mmol Kg⁻¹. These values are greater than those reported by Castille and Lawrence (1981) and Rodríguez (1981) of 680 (24‰) and 610 (21‰) mmol Kg⁻¹ respectively. The differences can be attributed to the different experimental conditions used in these studies, because it is known that factors like temperature, dissolved oxygen, molt stage, the size of the organisms, and the nutritional state have an influence on the hemolymph osmolality control of the penaeid shrimp (Williams 1960, Charmantier et al. 1994, Lignot et al. 1999). Our observations were conducted under standardized experimental conditions, and allow us to isolate the effect of temperature salinity fluctuations and repeated the experiments.

To evaluate the osmoregulatory capacity of *L. stylirostris* the values of the slopes of the relationship between the osmotic concentration of the medium and the hemolymph were compared with

Figure 4. Osmoregulatory capacity of blue shrimp *Litopenaeus stylirostris* acclimated at 23, 28 y 33°C and exposed to fluctuating salinities.

those obtained for other penaeids maintained in constant salinities, which had an interval of 0.11–0.73 (Díaz et al. 2001). A deviation of the slope of the isosmotic line reflects the degree of the regulation capacity (slope = 0 osmoregulator; slope = 1 osmoconformer). The values of the slopes of the juveniles acclimated to 23 °C, 28 °C, and 33 °C and exposed to decreasing salinity were 0.26‰, 0.17‰, and 0.11‰ and for ascending salinities 0.26‰, 0.19‰, and 0.18‰, respectively. The organisms with higher slopes as those maintained in 23 °C had a weak regulation and their osmoregulatory capacity was poor. According to Vernberg and Silverthorn, (1979) the temperature affect osmoregulatory capacity in crustacean by influencing water movement across cell membrane and in the uptake and loss of ions. The lower values of the slopes for the organisms maintained in 28 °C and 33 °C reflected that in these conditions the shrimps had a hyperosmoregulatory capacity in higher salinities and hyperosmoregulatory in lower salinity. Therefore, they can be characterized as strong regulators, because they adapt rapidly to the new salinities by increasing and decreasing the hemolymph osmotic concentration. For *L. stylirostris* subadults, Lemaire et al. (2002) obtained that reducing the temperature from 26 °C to 15 °C, there was a significant decrease of the osmoregulatory capacity in organisms maintained in con-

stant salinities. This different response can be considered from the adaptive point of view because the lower sensibility in the osmoregulatory capacity shown by the juveniles permits living in the lagoon-estuarine environment in which there are significant variations of temperature.

To optimize the culture of the blue shrimp in controlled conditions it is recommended that temperatures of approximately 28 °C be used. Because the best salinity has not been determined experimentally, we propose that 25‰ be considered as the optima for this species, because it corresponds with the isosmotic point determined for the blue shrimp. According to Pannikar (1968), in this condition the shrimps expend less energy for the maintenance of the osmotic gradient and therefore the growth increases when the organisms are cultivated in a stress-free environment.

ACKNOWLEDGMENTS

The authors thank the Laboratory El Camarón Dorado located in Huatabampo, Sonora, for the donation of the specimens used in this investigation. SIMAC-CONACYT gave the economical support to the projects 98011110606 and 200017509. We also appreciate the graphical material; elaborated by Jose M. Dominguez and Francisco J. Ponce from the Drawing Department of CICESE.

MOLECULAR PHYLOGENY OF SUPERFAMILY PENAEOIDEA RAFINESQUE-SCHMALTZ, 1815, BASED ON MITOCHONDRIAL 16S PARTIAL SEQUENCE ANALYSIS

ANA R. VÁZQUEZ-BADER,¹ JULIO C. CARRERO,² MARTÍN GARCÍA-VARELA,²
ADOLFO GRACIA^{1*} AND JUAN P. LACLETTE²

¹Dept. of Marine Ecology, Instituto de Ciencias del Mar y Limnología UNAM, A. P. 70305, 04510 México, D.F. México; ²Dept. of Immunology, Instituto de Investigaciones Biomédicas, UNAM, 04510 México D.F., México.

ABSTRACT Partial mitochondrial DNA sequences were analyzed to reconstruct the phylogeny of Superfamily Penaeoidea. In addition to 11 new 16S rRNA sequences generated for this study, 18 previously reported sequences (including 3 outgroups) were examined. The phylogenetic relationships estimated through maximum likelihood and neighbor joining methods supported the monophyly of the Superfamily Penaeoidea. Other findings, challenge our current classification schemes of the superfamily, and are presented as hypothesis for future work: the paraphyly of Penaeidae family and its close relationship to Solenoceridae; the close association between Aristeidae, Benthescymidae and Sicyoniidae questions their erection as separated families.

KEY WORDS: molecular phylogeny, 16S, mitochondrial DNA, Dendrobranchiata, Penaeoidea, shrimp

INTRODUCTION

Penaeoids shrimp of the Superfamily Penaeoidea Rafinesque-Schmaltz, 1815, are a diverse and abundant group with more than 400 species currently recognized within 49 genera representing 5 families: Aristeidae, Wood-Mason 1891; Benthescymidae, Wood-Mason 1891; Penaeidae, Rafinesque-Schmaltz 1815; Sicyoniidae, Ortmann 1898; and Solenoceridae, Wood-Mason 1891. Members of Penaeidae and Sicyoniidae are predominantly found in littoral water and include most of the shrimp commercially caught around the world in tropical and subtropical areas, whereas Aristeidae, Benthescymidae, and Solenoceridae are either deep benthic dwellers or members of the meso- and bathypelagic-fauna. Penaeoids shrimp show a diverse and complex morphology (i.e., the male and female genitalia), which have been recently reviewed by Pérez-Farfante and Kensley (1997).

The presence of a nauplius larval stage as well as the fossil record that placed penaeoids as the most basal group within decapods originated in the Permian-Triassic (Felgenhauer & Abele 1983) or in the Carboniferous (Schram 1977, Schram 1982, Dall et al. 1990). One hypothesis on the evolutionary relationships within Penaeoidea has been advanced (Burkenroad 1983), posing an Aeger-like organism as the common ancestor of all penaeoids, from which 2 branches arose: one early diverging branch leading to penaeids and sicyoniids, and a later emerging group resulting in the modern solenocerids, aristeids, and benthescymids.

In spite of their commercial, ecological, evolutionary, and taxonomical significance, no attempts have been made to elucidate the phylogeny of Superfamily Penaeoidea. A number of molecular studies have been carried out on the phylogeny and population genetics of Penaeidae (e.g., Bauer 1986, Bauer 1991, Palumbi & Benzie 1991, Machado et al. 1993, Bouchon et al. 1994, García et al. 1996, Baldwin et al. 1998, Ball et al. 1998, Tassanakajon et al. 1998, Tong et al. 2000, Chu et al. 2003). Other four families have not been approached through molecular phylogenetics.

This study is the first attempt to contribute a preliminary molecular phylogeny for the Superfamily Penaeoidea through analysis of partial sequences of 16S rRNA mitochondrial genes.

MATERIAL AND METHODS

Collection of Specimens

Eleven species representing the 5 families of Superfamily Penaeoidea that were included in the study: *Aristeus antillensis*, Milne Edwards and Bouvier 1909; *Aristacopsis edwardsiana*, (Johnson 1867); and *Penacopsis serrata*, Bate 1881 (collected during the oceanographic cruise BATO, Biota de los Arrecifes de la Plataforma y Talud continental en el noroeste del Banco de Campeche, Golfo de México); *Sicyonia burkenroadi*, Cobb 1971; *Sicyonia dorsalis*, Kingsley 1878; *Sicyonia brevirostris*, Stimpson 1871; *Farfantepenaeus duorarum* (Burkenroad 1939); *Litopenaeus setiferus* (Linnaeus 1767); and *Solenocera vioscai*, Burkenroad 1934 were caught during the oceanographic cruise SGM-6 (Banco y Sonda de Campeche, Golfo de México), both cruises were carried on board the R/V *Justo Sierra* (Instituto de Ciencias del Mar y Limnología, UNAM). *Gennadas* sp., and *Bentheogenema intermedia* (Bate 1888), were collected during the oceanographic cruise DgoMB (Deep Gulf of Mexico Benthos Study), carried on board the R/V *GYRE* (Texas A & M, University), and identified by M. Wickstein. All samples consisted of a piece of pleopod (70–80 mg) preserved either in 70% ethanol or in liquid nitrogen.

DNA Isolation and Amplification

DNA extractions were carried out using the Blood & Cell Culture DNA Mini Kit (Qiagen), following the instruction from the manufacturer. A 418-bp fragment of the 16S gene was amplified through polymerase chain reaction performed in a BioRad Mastercycler Gradient. The 50- μ l reaction mixture contained: 0.2 mM each dNTP (Gibco BRL), \times 1 Amplification Buffer (Invitrogen), 1 mM MgSO₄ (Invitrogen), 1 μ M each primer (Invitrogen), 0.5 unit Platinum Pfx DNA Polymerase (Invitrogen), and 80–100 ng template DNA (undiluted or diluted 10–20 \times in ddH₂O). Two primers were developed for this study and used to amplify the homologous 3' end of 16S mitochondrial region: Forward E 5'-TAGAGAATTCGACCGTGCGAAGGTAGC-3'; Reverse X 5'-TTGAGAGCTCATTCAACATCGAGGTGGC-3'. These primers contained EcoRI and XhoI sites, respectively, to facilitate ligation into standard plasmids for sequencing, although, in this report all sequencing was carried out from PCR products. Cycling condi-

*Corresponding author. E-mail: gracia@mar.icmyl.unam.mx

tions were: 94°C/4 min initial denaturing step followed by 30 cycles of 94°C/1 min, 45 to 55°C/1 min, 72°C/1 min, and final extension step of 72°C/10 min. Doubled-stranded PCR products were purified from gel (Montage DNA Gel Extraction Kit, Millipore) or directly from the PCR reaction mixture (Microcon-PCR Filter Unit, Millipore).

Purified PCR products (10 µl) were sequenced in both directions using the ABI-Big Dye-Terminator Sequencing Kit (Applied Biosystem Inc.) under manufacturer-recommended reaction conditions.

Sequence Analysis

All nucleotide sequences were aligned using Clustal W 1.5 c (Thompson et al. 1994) and then manually adjusted. Phylogenetic analysis was initially carried out with PAUP* 4.10 (Swofford 2003). To determine which model of sequence evolution best fitted the data set, a nested likelihood ratio test was performed using Modeltest program version 3.0 (Posada & Crandall 1998). After the evolution model was determined, phylogenetic relationships were inferred using maximum likelihood (Felsenstein 1981). Fifty random taxon addition heuristic searches with tree bisection-reconnection branch swapping were conducted. To support the relationships among the taxa 100 bootstrap searches were performed (Felsenstein 1985). Figure was prepared in part using the programs RETREE and DRAWGRAM from PHYLIP (Felsenstein 1999). Phylogenetic relationships were also estimated using neighbor-joining (NJ) analysis (Saitou & Nei 1987). NJ analysis was performed using Jukes-Cantor and pair-wise deletion options (MEGA 2.0, Kumar et al. 1993). Bootstrapping (1000 replicates) was performed to assess the confidence level at each branch.

RESULTS

In addition to 11 new mitochondrial 16S partial sequences generated for this study, another 15 partial sequences from 5 different Penaeoidea families, and 3 outgroup taxa were also included. Our dataset consisted of 29 sequences, 303–374 bp long. New sequences have been deposited in GenBank under accession numbers shown in Table 1.

Aligned sequences were considerably AT-rich (75%). Base composition was A = 0.37, C = 0.026, G = 0.17, and T = 0.38. The average distance in all Penaeoidea species was 0.137 ± 0.12 and ranged from 0.001 between *Sicyonia dorsalis* and *Aristaeopsis edwardsiana* to 0.234 between *Aristeus antillensis* and *Farfantepenaeus duorarum* as well as *A. antillensis* and *Litopenaeus setiferus* (Table 2).

The likelihood ratio test indicated that the model with best fit for the data set was the Hasegawa-Kishino-Yano model (HKY; Hasegawa et al. 1985), with a heterogeneity rate: (+G; Yang 1994); a transition/transversion ratio of 2.1355; a gamma shape parameter of 0.44; and with invariable sites (+I) of 0.2147. Maximum likelihood analysis using this model yielded two trees with a $-2 \ln$ likelihood of 2942.592. Differences among both trees were the position of *Aristeus antillensis*, *Aristaeopsis edwardsiana*, and *S. dorsalis*. Despite the number of polytomies in the ML tree (Fig. 1), several features can be observed, being the monophyly of the Penaeoidea superfamily the most conspicuous, well apart from the 3 outgroup species: *Synalpheus pectiniger*, *Cataleptodius floridanus*, and *Nantho poressa*. Surprisingly, the Penaeidae family appeared as a paraphyletic assemblage formed by at least 3 clades. Clade A, formed by 9 species within 6 genera (according to Pérez-Farfante & Kensley 1997) including the three species of American

TABLE 1.

List of the Superfamily Penaeoidea species used in this study.

Family/Species	Zoogeographic Distribution	GenBank Accession Numbers
Aristeidae

Abbreviation for the species names are shown in brackets.

* Species sequenced for this work.

WA, Western Atlantic; EA, Eastern Atlantic; EP, Eastern Pacific; IP, Indo-West Pacific.

Farfantepenaeus and the two *Litopenaeus* species, the Indo-West Pacific *Melicertus canaliculatus* and *Marsupenaeus japonicus*, as well as 2 separated species, *Penaeus monodon* and *Femmeropenaeus indicus*, which were not resolved in the ML tree, although clearly separated from the other genera. Clade B consisted of 2 Indo-West Pacific species *Trachysalambria curvirostris* and *Parapenaeopsis hardwickii*, and the western Atlantic *Xiphopenaeus kroveri*. Clade C included *Parapenaeus fissurus* and *Metapenaeopsis barbata* from the Indo-West Pacific and *Penaeopsis serrata* from the western Atlantic, unexpectedly associated with the species of the Solenoceridae family: *Solenocera koelbeli* and *S. crassicornis* from the Indo-West Pacific, and *S. vioscai* from the Western Atlantic. The only species of the Penaeidae family that appeared isolated was *Metapenaeus ensis*, which showed the highest genetic distances within Penaeidae (see Table 2). Another remarkable feature from the ML tree was the grouping of species belonging to families Sicyoniidae, Benthescymidae, and Aristeidae in Clade D. Finally, the three outgroup species appeared

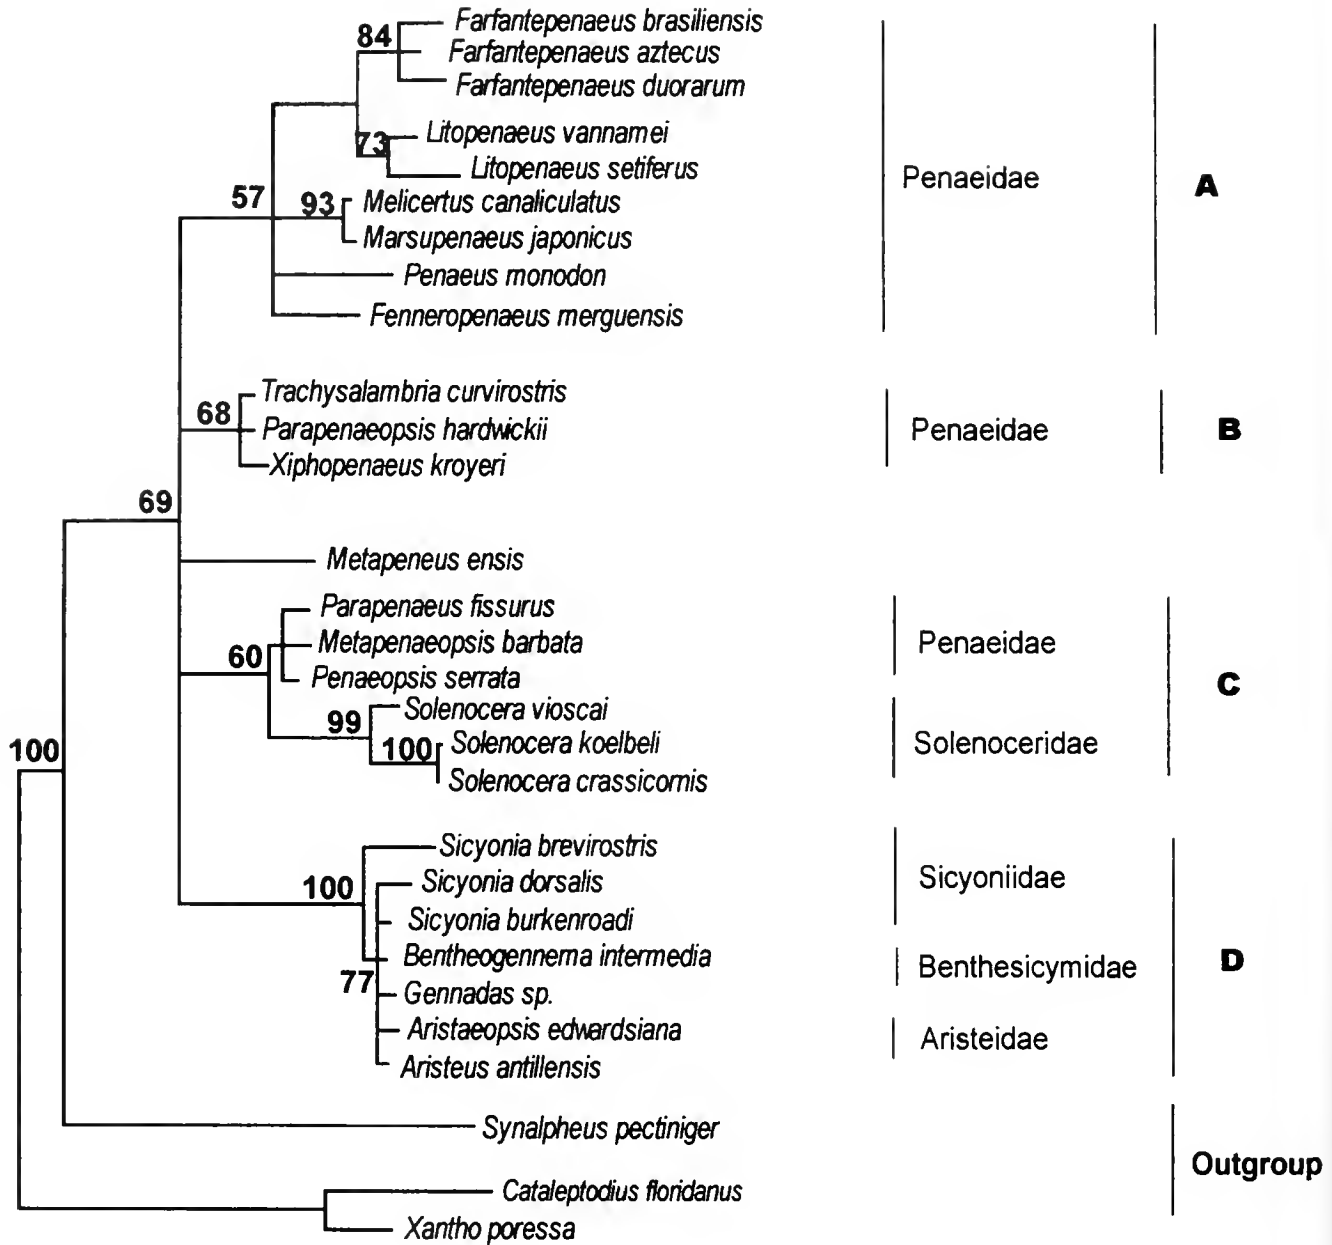

Figure 1. Maximum likelihood (ML) tree from 16S rRNA data under the best-fitting model HKY + G + I. Bootstrap values are shown as percentages and are based on 100 replicates. Branches without bootstrap numbers mean that the bootstrap values are below 50%. Labels A, B, C, and D indicate the major clades of the Superfamily Penaeoidea.

well separated, with the caridean *Synalpheus pectiniger* as the sister for all Superfamily Penaeoidea. The average genetic distances within each clade was: A = 0.108 ± 0.011 , B = 0.094 ± 0.012 , C = 0.075 ± 0.010 , and D = 0.025 ± 0.004 , whereas the average between 2 clades was: A-B = 0.151 ± 0.016 , A-C = 0.133 ± 0.014 , A-D = 0.191 ± 0.021 , B-C = 0.125 ± 0.015 , B-D = 0.174 ± 0.021 , and C-D = 0.159 ± 0.019 .

The lack of resolution in some branches of the ML tree led us to carry out a NJ analysis. Like the ML, the NJ tree provided evidence supporting the monophyly of Superfamily Penaeoidea, and showed a similar arrangement of species in four clades (Fig. 2). However, in the NJ tree, clades A, C, and D formed a larger

assemblage separated from clade B, which was placed as the sister group of all other members in the superfamily. Again, *P. fissurus*, *M. barbata*, and *P. serrata* were closely associated with the species of the Solenoceridae family. *M. ensis* appeared outside the major grouping of penaeids, although in the NJ tree it was related to clade D, formed by the species of families Aristeidae, Benthescymidae, and Sicyoniidae. Again, the three outgroup species appeared clearly separated from the Penaeoidea.

DISCUSSION

Despite the limited information to solve the relationships with these partial 16 S sequences, several general considerations

Figure 2. Neighbor-joining (NJ) tree from 16S rRNA data. Bootstrap values are shown as percentages and are based on 1,000 replicates. Branches without bootstrap numbers mean that the bootstrap values are below 50%. Labels A, B, C, and D indicate the major clades of the Superfamily Penaeoidea.

emerged from both analyses and might be erected as hypothesis for future work using larger sequence data: (1) The monophyly of Superfamily Penaeoidea; (2) The paraphyly of Penaeidae family and its close relationship to Solenoceridae family; and (3) Aristeidae, Benthescycymidae and Sicyoniidae form a compact group with small genetic distances and might not deserve erection as separated families.

The relatively large genetic divergence observed within family Penaeidae (Clades A-C) seems to be in agreement with morphologic traits described long ago (Burkenroad 1936, Burkenroad 1983, Kubbo 1949). Members of clade A showed the greatest mean divergence (0.0108); taken as a natural group, they might be characterized morphologically by the presence of an epipod on third maxilliped, pleurobranchiae on fifth pereopod, ventral and

dorsal rostral teeth, as well as by the absence of branchiostegal, pterygostomial and parapenaeid spines, and transverse and longitudinal sutures on carapace. All but the two species of *Litopenaeus* within clade A, show a symmetrical and semiclosed petasma without distolateral projections, uninvginated and unpaired seminal receptacles, simple spermatophore without accessories, and thelycum closed with two lateral plates (with the exception of *Marsupenaeus*, which shows a thelycum with one plate, and spermatophore with accessories). The *Litopenaeus* species have a semiopen petasma and thelycum without seminal receptacles, and a complex spermatophore with accessories. Our results are in agreement with a previous study based on 16S mitochondrial DNA (Maggioni et al. 2001), proposing similar differentiation between *Farfantepenaeus* with closed thelycum and semiclosed petasma versus *Litopenaeus* with open thelycum and semiopen petasma.

Clade B formed by *Trachysalambria*, *Parapenaeopsis*, and *Xiphopenaeus* appeared divergent from the other penaeids. They are morphologically different from Clade A by the absence of pleurobranchiae on pereopods 4 and 5, the lack of epipod on third maxilliped, presence of rostral teeth only on dorsal side, symmetrical and semiclosed petasma with hornlike or spoutlike distolateral projections, closed thelycum with one lateral plate, and the seminal receptacles paired and invaginated.

Clade C differs from Clades A and B by the lack of pleurobranchia only on fifth pereopod and the presence of pterygostomial and parapenaeid spines. However, members of clade C are morphologically similar to those in clade B in several sexual characters: symmetrical and semiclosed petasma with invaginated and paired seminal receptacles, closed thelycum with one plate and simple spermatophore without accessories (except for *Metapenaeopsis* which shows asymmetric petasma and uninvginated and unpaired seminal receptacles).

Association of family Solenoceridae deserves further attention because the uniqueness of their postorbital spine within Superfamily Penaeoidea. Relationships between solenocerids and penaeoids suggested in our analyses were surprising, although are not without precedent. Burkenroad (1983) proposed that some genera within Solenoceridae (e.g., *Haliporus*), are closer to Aristeidae (by the presence of appendix interna, the two arthrobranchiae on first maxilliped and the mesial tubercle on optic calathus), whereas others (e.g., *Solenocera* and *Pleoticus*) resemble Penaeidae by the presence of pterygostomial, branchiostegal and ocular spines, an orbital scale, similar branchial formula, a semiopen petasma, and an open thelycum. Our results certainly differ from previous systematic studies and might suggest that morphologic characters used to differentiate among families within Superfamily Penaeoidea, have been over-emphasized. Further molecular analyses with larger sequence data and including other genera of Solenoceridae, will be necessary to elucidate the status of this family.

The apparently anomalous position of *M. ensis* within penaeids seems to agree with some atypical morphologic characters like the petasma with distolateral projections, the lack of pleurobranchia and exopod on fifth pereopod, the fifth male pereopod modified and the presence of basal spine on third maxilliped and pereopods 2–3. On this respect, previous study using allozyme markers (Tam & Chu 1993) have also revealed considerable genetic differences between *Metapenaeus* and other subgenera of *Penaeus*.

The largest genetic distance (mean = 0.175), was found between the compact group (Clade D) formed by Sicyoniidae, Benthescymidae, and Aristeidae and the other penaeoid families. Our results strongly suggest that the 3 families are closely related and separated from families Penaeidae and Solenoceridae, however, the status of each family within Clade D will require further molecular analysis. Aristeidae and Benthescymidae share a similar branchial formula and presence of a reduced prosartema, but differ in features of the genitalia: *A. antillensis* and *A. edwardsiana* show open thelycum and petasma, whereas *B. intermedia* and *Gemadas*, sp. have closed petasma and thelycum with invaginated and paired seminal receptacles. Nevertheless, the seminal receptacles and the spermatophores in Benthescymidae are not homologous with Penaeidae and Sicyoniidae (Burkenroad 1936, Bauer 1986, Bauer 1991). Species of *Sicyonia*, resemble those of Penaeidae in some genitalia characteristics, whereas with Aristeidae and Benthescymidae share the lack of exopods in the pereopods 1–5, and absence of the ocular scale. On the other hand, sicyoniids possess morphologic characters that otherwise are unique to Penaeoidea: a single pleurobranchia on the fifth pereopod, uniramous third to fifth pleopods, lack of exopods in all pereopods, closed petasma with distal, sclerotized projections, without true spermatopores, and thelycum with lanceolate median plate.

A recent molecular analysis of the phylogenetic relationships of genus *Penaeus* s.l. based in partial sequences of 16S and Cytochrome oxidase I (COI) is consistent with our results within clade A (Lavery et al. 2004).

As indicated earlier, the value of this study is to direct the attention to three major questions about Superfamily Penaeoidea, and in particular, about the status and relationships among families. Additional molecular studies are needed to provide stronger evidence on the evolutionary history within the superfamily.

ACKNOWLEDGMENTS

The authors thank P. de la Torre, A. Gómez, and C. Padilla for the technical support and field work. Special gratitude is extended to D. Piñero for kindly introducing me to Molecular Biology Research (A. R. V. B). This work was partially supported by research grants from CONACYT (41693-M: J. P. L. and J. C. C.), DGAPA UNAM (IN206102-3: J.P.L. and J. C. C.) and Fundación Miguel Alemán, A.C. (J. P. L.).

EFFECTS OF FEEDING LEVEL ON THE GROWTH, ENERGY BUDGET AND BODY BIOCHEMICAL COMPOSITION OF CHINESE SHRIMP *FENNEROPENAEUS CHINENSIS*

GUOQIANG HUANG, SHUANGLIN DONG* AND FANG WANG

Mariculture Research laboratory, Fisheries College, Ocean University of China, Qingdao 266003, People's Republic of China

ABSTRACT Chinese shrimp *Fenneropenaeus chinensis* with wet weight of 3.0 g, 8.0 g, 14.2 g, and 19.0 g were fed at 5 feeding levels of 0, 0.5%, 1.0%, and 1.5% of the body weight, and *ad libitum* to investigate the growth and food conversion efficiency under different feeding levels. The relationship among daily growth coefficient (DGC) (in terms of wet weight, dry weight, protein, and energy), initial body weight (IBW) and feeding level (FL) was well described with the dualistic linear model $DGC = B_0 + B_1 \times IS_w + B_2 \times FL$. The relationship between food efficiency (FE) in terms of dry weight, protein, and energy of shrimp with different body weight and feeding level was described with the model $FC = B_0 + B_1 \times \ln FL$. DGC and IBW were negatively correlated, regardless of term of wet weight, dry weight, protein, or energy of the shrimp body weight. The maintenance feeding level (MFL) of Chinese shrimp was positively linear correlated to IBW and the maintainable energy intakes (MEI, J/g BW/d) for shrimp with different IBW were: 3.0 g, 218.3 J/g BW/d; 8.0 g, 213.5 J/g BW/d; 14.2 g, 207.5 J/g BW/d; 19.0 g, 202.9 J/g BW/d.

KEY WORDS: feeding level, daily growth coefficient, energy budget, body biochemical composition, Chinese shrimp

INTRODUCTION

Either in natural environment or culture ponds, the crustacean experience starvation and under-nutrition occasionally. Studies have found that starvation caused low metabolic rate (Wallace 1973, Regnault 1981, Whyte et al. 1986, Chappelle et al. 1994) and high body moisture content (Dall 1974, Cuzon et al. 1980, Barclay et al. 1983, Sasaki et al. 1986, Stuck et al. 1996a, Wu & Dong 2000, Wu & Dong 2002a, Wu & Dong 2002b, Lin et al. 2004) in crustacean. Other items of shrimp body composition such as protein, lipid, and energy content decrease gradually through the fasting period (Barclay et al. 1983, Stuck et al. 1996a, Wu et al. 2000, Wu & Dong 2002a, Wu & Dong 2002b, Lin et al. 2004). Positive correlation existed between the growth and feeding level in shrimp and crabs (Bartley et al. 1980, Miao & Tu 1993, Gu et al. 1996). Besides, the feeding level affected body composition, such as moisture, protein, and lipid content of American lobster *Homarus americanus* (Bartley et al. 1980) and redclaw crayfish, *Cherax quadricarinatus* (Gu et al. 1996). To explore the physio-ecologic characters of shrimp in different nutritional conditions, the responses of growth, FE, energy budget, body biochemical composition, and body gross energy content to feeding levels of Chinese shrimp, *Fenneropenaeus chinensis* with different body weight, were studied in this experiment.

MATERIALS AND METHODS

Diet Used in This Experiment

The diet used in this study was a commercial formulated shrimp pellet (Sea-Horse Brand; Producer: Fujian Mawei Unite Feed Ltd. Co., China). The proximal composition of the diet was: moisture, 7.70%; crude protein, 42.57%; crude lipid, 9.93%; ash, 10.75%; and gross energy 19.23 KJ.g⁻¹.

Rearing Conditions

Chinese shrimp were kept in glass aquaria (45 × 30 × 30 cm³, water volume of 35 dm³), and each rearing unit was stocked with 1 shrimp. The room temperature was thermostatically controlled,

and water temperature was 25° ± 05°. Aeration was provided continuously and 1/2 to 2/3 of water was exchanged every other day. Seawater used in the experiment was filtered by composite sand filter. During the experiment, dissolved oxygen water was maintained above 5.5 mg/L, pH was about 8.0, the water salinity was between 30‰ to 33‰, and the photoperiod of 14 hours of light: 10 hours of darkness was used.

Source and Acclimation of Shrimp

The experiment was carried out at the Mariculture Research Laboratory, Ocean University of China, People's Republic of China. The shrimp used in the experiment were collected from the Tianheng Shrimp Farm, Qingdao. Prior to the experiment, the shrimp were transferred into aquaria and underwent a 7-day acclimatization period during which the shrimp were fed with the formulated diet (FD) at satiation level twice daily (at about 6:00AM and 6:00PM).

Experiment Design

After 24 hours starvation, shrimp with wet weight of 3.0 ± 0.2 g, 8.0 ± 0.5 g, 14.2 ± 0.9 g, and 19.0 ± 1.4 g (Mean ± SD) were selected from acclimated shrimp. For every body weight size, shrimp were fed at 5 feeding levels (0, 0.5%, 1.0%, 1.5% wet body weight, and satiation level) for 28 days. Six groups for every treatment were designed and a complete randomized block design was used to arrange aquaria.

Samples Collection and Analysis

Three groups (8 shrimp each) were sampled from the acclimated shrimp to determine the initial body composition of experimental shrimp. After 28 days all groups of shrimp were starved for 24 hours, and then sampled. The treated shrimp were pooled as three samples randomly (2 shrimp for a sample to get enough material for analyzing) and there were 60 samples (3 per treatment) of final shrimp.

During the course of the experiment the daily food supplied to shrimp was recorded and uneaten food and feces were collected within 3 hours after feeding. Shrimp and food were weighted using an electronic scale after carefully blotted with paper towel to remove excess moisture.

TABLE 1.

The relationship among the daily growth coefficient (DGC), feeding levels (mg/g shrimp/day), and initial shrimp weight (g).

Model	DGC = B ₀ + B ₁ × FL + B ₂ × IBW (n = 120)					
	B ₀ (Mean ± SE)	B ₁ (Mean ± SE)	B ₂ (Mean ± SE)	R	F	P
DGC _w	-0.236 ± 0.028	0.021 ± 0.002	0.001 ± 0.001	0.780	90.63	<0.01
DGC _d	-1.227 ± 0.059	0.067 ± 0.003	0.024 ± 0.004	0.888	218.94	<0.01
DGC _p	-1.487 ± 0.073	0.078 ± 0.004	0.033 ± 0.005	0.879	198.33	<0.01
DGC _e	-1.611 ± 0.072	0.083 ± 0.004	0.037 ± 0.004	0.893	231.53	<0.01

After weighing all samples of shrimp, feces, and food were dried in an oven at 70° to constant weight, homogenized with a glass mortar, and stored at -20°. Before chemical compositions were analyzed, the samples were re-dried at 70° to constant weight.

Nitrogen content was measured using the MicroKjeldahl methods and the crude protein content was calculated (N × 6.25) (AOAC, 1984). Crude lipid was determined by the Soxhlet method (AOAC, 1984), ash was determined by combusting dry samples in a muffle furnace at 550 for 12 h (AOAC, 1984), and the gross energy content of dry samples was determined with PARR1281 bomb calorimeter (PARR Instrument Company, USA). Analyses of each sample were conducted in triplicate (3 subsamples for each sample).

Calculation of Data

The FE, % was calculated as follow:

$$FE = 100 \times (FBW - IBW) / I$$

Where the shrimp body weight was dry weight (DW, g), the diet was expressed in terms of dry weight (DW, g), FBW was the final shrimp weight, IBW was the initial shrimp weight, I was the quantity of ingested diet during the experiment period.

All samples in terms of dry weight (DW, g), protein (P, g), and energy (E, KJ) were used to calculate the FE (FE_d, FE_p, FE_e) respectively.

The DGC_w was calculated as follow (Covey 1992):

$$DGC = (FBW^{1/3} - IBW^{1/3}) / D$$

Where D was the days of experiment period. All samples in terms of dry weight (DW, g), protein (P, g), and energy (E, KJ) were used to calculate the DGC (DGC_d, DGC_p, DGC_e) respectively.

The feeding level (mg/g BW/d) was calculated as follow:

$$FL = 2 \times 1000 \times I / (FBW + IBW) / D$$

Items in the energy budget equation (C_e = G_e + F_e + E_e + U_e + R_e) (Klein 1975) of shrimp were calculated as follow:

$$\text{Energy intake (I}_e\text{)} = I_d \times GE_d$$

$$\text{Growth energy (G}_e\text{)} = FS_e - IS_e$$

$$\text{Energy of feces (F}_e\text{)} = F_d \times GE_f$$

$$\text{Energy of exuviae (E}_e\text{)} = E_d \times GE_e$$

$$\text{Energy of excretion (U}_e\text{)} = U_N \times 24.83$$

$$\text{Energy of metabolism (R}_e\text{)} = I_e - G_e - F_e - E_e - U_e$$

Where GE_d, GE_p, and GE_e were gross energy of diet, feces, and exuviations respectively, F_d, E_d, and U_N were dry weight of diet, dry weight of feces and nitrogen of excretion respectively, FS_e and

IS_e were energy content of final shrimp and initial shrimp. 24.83 means the energy cost of 1g nitrogen excreting (in form of NH₃) is 24.83 KJ. The daily unit body weight energy partitions were calculated by dividing 28 × (FBW + IBW)/2.

The nitrogen of excretion (U_N) was calculated as the follow formula (Levine & Sulkin 1979; Lemos and Phan 2001):

$$U_N = I_N - G_N - F_N - E_N$$

Where I_N, G_N, F_N, and E_N were nitrogen content in ingested diets, body growth, feces and exuviations.

The percentage of growth energy (G_e) in energy consumption (C_e) was calculated as 100 × G_e / I_e, and the percentages of F_e, E_e, U_e, and R_e in I_e were calculated similarly.

Statistical Analysis

Statistics were performed using SPSS10.0 statistical software with possible differences among diet treatment being tested by 1-way ANOVA. Tukey's b-multiple range tests were used to test differences between treatment groups of the same size. The square-root transformation of the sine-arc before analyzing the values given in percentages was used. Differences were considered significant at a probability level of 0.05. The curve estimation was used in regression analysis.

RESULTS

Relationship Between Daily Growth Coefficient and Feeding Level

The dualistic linear model (DGC = B₀ + B₁ × IS_w + B₂ × FL) could describe the relationship among the DGC of Chinese shrimp,

its initial body weight (IBW) and feeding levels (FL) (Table 1). Whatever the shrimp body weight and feeding levels were expressed by wet weight, dry weight, protein or energy, the values of parameter B_1 and B_2 were positive, which means the DGC of shrimp were positively linear correlative to FL and IBW.

The Relationship Between the Food Efficiency and Feeding Level

The FE of Chinese shrimp was significantly correlative to FL, and the linear model $FE = B_0 + B_1 \times \ln FL$ could describe the relationships between FE and $\ln FL$ of the shrimp with four body weight sizes (Table 2). However, with the decreasing of the initial body weight the correlativity (see R^2 in Table 2) was improved.

The Energy Allocation of Chinese Shrimp Fed at Different Feeding

Table 3 denoted the models of energy allocation of Chinese shrimp with different body weight at different feeding levels. The maximal of feeding levels was different in shrimp with different

body weight, and it declined when the body weight rose (Table 3). When the shrimp were fed at the satiation level, the average gross energy intake of single shrimp over the experimental period was 1.74 KJ, 3.37 KJ, 3.89 KJ, and 5.43 KJ respectively for shrimp with different IBW. The fasting energy losses during the experimental period varied from 8.6 KJ to 43.2 KJ according to different sizes (Table 4). The energy loss through respiration (%IE) was greater in small shrimp than that in large shrimp, and energy loss of exuviations (%IE) was greater in large shrimp than that in small shrimp (Table 4). For daily unit body weight energy allocation (J/g BW/d), I_e , G_e , R_e , F_e , and U_e increased as FL increased, regardless of IBW. It seemed that FL did not significantly affected E_e in all IBW.

The Biochemical Composition and Gross Energy Content of Final Shrimp Fed at Different Feeding Levels

The differences of biochemical composition of four size shrimp fed with different feeding levels were listed in Table 5. In the same

TABLE 5.

IBW, Initial body weight (g); FL, Feeding level (mg/g shrimp/day).

Values without same letters in the same parameter of the same Body wet weight were significantly different from each other.

The superscript letters a through e in this table were markers of differences of values.

TABLE 6.

The relationship between maintainable feeding level (MFL, mg/g shrimp/day) and initial body weight (IBW).

Model	Terms of IBW				
		Wet weight	Dry weight	Protein	Energy
MFL = $A_0 + A_1 \times \text{IBW}$					
Parameters	A_0	11.5	18.3	19.0	19.5
	A_1	-0.05	-0.36	-0.42	-0.45

size, the body moisture contents of the shrimp fed low feeding level were higher than that of initial shrimp, and it decreased with the increasing of feeding level. The range of the body moisture content of all treatments was from 75.1% to 87.9%. In low FL treatments, the protein content, lipid content and gross energy of shrimp body were significantly lower than those of the initial shrimp, and they increased along with the increasing of feeding level. The body protein content, lipid content and gross energy of four sizes shrimp fed at satiation level (from small to large) were listed below: protein, 15.2%; 19.3%; 17.9%; and 16.4%; lipid, 2.1%; 2.1%; 1.8%; and 2.8%; gross energy, 4.5KJ/g; 4.7 KJ/g; 4.6 KJ/g; and 5.1 KJ/g. It was found that no significant difference existed among different body weight sizes in the protein content, lipid content and gross energy when the shrimp were fed at satiation level.

It was found in the starved and low feeding level treatment that the body moisture content of final shrimp was higher than that of initial shrimp and high feeding level treatment. But the body protein content, lipid content and gross energy of starved and low feeding level treatment were lower than those of initial shrimp and high feeding level treatment. These indicated that the ingested nutrients and energy could not meet the requirement of minimal metabolism in low feeding level treatment, which resulted in the decreasing of body nutrient and energy deposits.

Energy Loss of Fasting Shrimp and Maintainable Feeding Level

It was found that the total energy loss for individual shrimp during the experimental period was directly related to IBW. For unit body weight energy loss per day, the small shrimp (3.0g and 8.0g) lose more energy than large shrimp (14.2 g and 19.0 g). R_c accounted for most of the energy loss regardless of IBW. The relationship between MFL and IBW could be achieved from the relationship between DGC, FL, and IBW (supposed DGC = 0). A linear model was achieved (Table 6) and it inferred that MFL was inversely correlated to IBW. The MIE, (J/g BW/d) for shrimp with different IBW is listed in Table 7. The linear model indicated MIE was also inversely correlated to IBW.

DISCUSSION

Growth Model of Chinese Shrimp

In this study, it was found that the compound relationship among the special growth rate DGC of Chinese shrimp, feeding level (FL) and initial body weight (IBW) were duality linear. It is to say that in every body weight size the DGC and FL were significantly linearly correlated. Similar positive correlations between growth and ration size have been found in studies on shrimp and crabs (Lee 1971, Venkataramiah et al. 1975, Caillouet et al. 1976, Sedgwick 1979, Bartley et al. 1980, Viayaraghavan et al.

1982, Maguire & Leedow 1983, Gu et al. 1996). In this model, when DGC was calculated in wet weight, B_1 was less than one third and B_2 was less than one twentieth of those when DGC calculated in dry weight, protein, or energy (Table 1). This particularity resulted from variability of body moisture content in different conditions. The increase of body moisture content in under-nutritional condition and the reduction of body moisture content in nutrition satiation condition would conceal the alteration of wet body weight.

Effect of Feeding Level on Energy Allocation

In this study, daily unit body weight energy allocation (J/g BW/d) of R_c and U_c were positively correlated to FL regardless of IBW. This result was in agreement with results found in studies on the relationship between metabolic rate or excrete rate and feeding level or ration size in other crustacean (Hewitt & Iving 1990, Du Preez et al. 1992, Burggren et al. 1993, McGaw & Reiber 2000, Peck & Veal 2001). Directly positive relationship existed between G_c and FL. This relationship supported the relationship between DGC and FL. It indicated that the more shrimp ate, the faster the shrimp grew. This was also similar to other studies (Lee 1971, Venkataramiah et al. 1975, Caillouet et al. 1976, Sedgwick 1979, Bartley et al. 1980, Viayaraghavan et al. 1982, Maguire & Leedow 1983, Gu et al. 1996).

Effect of Feeding Level on Body Composition

In this study, starvation and low feeding levels caused increase in body moisture content and reduction in protein, lipid, and energy content of Chinese shrimp, which is in agreement with previous studies on Chinese shrimp (Wu & Dong 2002a, Wu & Dong 2002b) and other species of crustacean (Dall 1974, Cuzon et al. 1980, Barclay 1983, Sasaki et al. 1986, Stuck et al. 1996a, Lin et al. 2004). It could be concluded that starvation and limited food supply would bring similar effects on body composition caused by other environmental stress such as pollution (Wang & Stickle 1988), infection (Stuck et al. 1996b), and nutrition stress (Lim 1997, Stuck et al. 1996a). There was an inverse relationship between body moisture content and growth, whereas the protein, lipid, and energy content were directly related to growth. Similar results have been found in other studies (Stuck et al. 1996a, Lim 1997). Besides, the protein, lipid, and energy content were negatively correlated to moisture content. Weatherley (1981) proposed to form a significant relationship between moisture and other composition such as protein, lipid, and energy in fish. It was easy to determine the moisture content. Then other composition would be easily calculated. But this method is unsuitable for shrimp. Except

TABLE 7.

Maintainable energy intake (MIE, J/g BW/d) for shrimp.

IBW	MIE			
	Wet weight	Dry weight	Protein	Energy

8.0 ± 0.5	213.5	296.5	300.8	305.8
14.2 ± 0.9	207.5	253.6	250.7	252.1
19.0 ± 1.4	202.9	220.4	220.4	210.6

Wet weight, dry weight, protein, and energy means maintain zero wet weight, dry weight, protein, and energy growth or loss.

for nutritional conditions, the molting cycle also affected the body composition of shrimp (Read & Caulton 1980).

Maintenance Feeding Level of Chinese Shrimp

The metabolic level of unit body weight of animals decline along with the rising of body weight, therefore the MFL of their unit body weight is negatively correlated to their actual body weight. It could be concluded from the values of A_1 that MFL is positively linear correlated to IBW, regardless of terms described in the data. The MEI (J/g BW/d) is inversely related to IBW. It is also a sign of reduction in metabolic level as BW increased. This

fact correlates with results of other studies (Nelson et al. 1977, Emmerson 1985, Dong et al. 1994, Zhang et al. 1998). It was found that maintenance energy intakes (MIE) are higher than unit body weight energy loss of fasting shrimp. For large shrimp, the difference was more obvious. This could attribute to the increase of metabolic rate after ingestion of food and the decrease of unit body weight energy loss.

THE ORIGIN OF THE REGULATORY LIMITS FOR PSP AND ASP TOXINS IN SHELLFISH

JOHN C. WEKELL,¹ JOHN HURST² AND KATHI A. LEFEBVRE³

ABSTRACT Understandably, commercial and recreational seafood harvesters are interested in how regulatory limits are set for various toxins in seafood. Here we summarize the origins of the safety levels for paralytic shellfish poisoning (PSP) and amnesic shellfish poisoning (ASP) toxins. PSP toxins consist of a suite of neurotoxins identified as saxitoxin, gonyautoxin, and their derivatives. The regulatory limit for these toxins (80 µg STX equiv. / 100 g shellfish) was established in the 1930s and is based on bioassays measuring toxic activity in mice. Amnesic shellfish poisoning (ASP) is a more recently discovered syndrome caused by one toxin, domoic acid (DA). It was identified in 1987 and the regulatory limit of 20 µg/DA g tissue was established in the following year, based on the estimated DA dosage levels consumed by the first human victims of ASP. This study attempts to preserve the history of the origin of these regulatory limits, both of which have not changed and have effectively protected consumers of commercial seafood since their implementation.

KEY WORDS: paralytic shellfish poisoning, amnesic shellfish poisoning

INTRODUCTION

At seafood safety meetings, scientists and policy makers are frequently asked by recreational and commercial seafood harvesters about the origins of the regulatory limits set for marine biotoxins in particular seafood's. In the case of paralytic shellfish poisoning (PSP) toxins, the regulatory limit (80 µg/100 g) was established over 60 years ago and its origin is beginning to be lost to the fog of history. Amnesic shellfish poisoning (ASP) caused by domoic acid (DA), on the other hand, is a relatively new syndrome. The first DA poisonings were observed in 1987 in eastern Canada and the regulatory limit for DA in seafood (20 µg/g) was established by Health Canada in the late 1980s. With the discovery of DA in finfish and shellfish on the west coast of the United States in 1991 (Work et al. 1993), the US Food and Drug Administration also adopted the Canadian value.

The regulatory limits for PSP and ASP toxins evolved quite differently. The chemical structures and toxicology of the PSP toxins were only vaguely understood in the 1930s when the limits were developed. In contrast, the chemical structure of DA had already been long established (Takemoto et al. 1966) before its regulatory limit in shellfish was set by Health Canada in 1987. In fact, extracts of marine algae that contained domoic acid and a related congener, kainic acid, had been used as an antihelminthic for children in Japan (Baslow 1969). However, specific information about the toxicity of DA at higher doses in adults was obtained following the first ASP outbreak in 1987. In an effort to preserve the history of the origin of the regulatory limits for PSP and ASP, we have prepared a brief note describing how these values were first derived based on sound epidemiology and toxicology.

Regulatory Limit for PSP Toxins (80 µg STX Equiv. 100 g⁻¹ Shellfish)

The Toxic Syndrome, PSP

PSP is caused primarily by the consumption of molluscan shellfish that have accumulated PSP toxins as a result of filter-feeding on toxic dinoflagellates (Shumway et al. 1988). In some rare cases finfish and crabs have also been implicated as vectors of PSP toxins. Saxitoxin is the most toxic of the PSP toxins (Oshima 1995). At least 16 variants of this basic structure have been iden-

tified and the variants range in toxicity from high (saxitoxin) to almost nontoxic (the sulfonated toxins). The composition of the suite of PSP toxins found in shellfish is both dependent on the specific phytoplankton (*Alexandrium* sp.) consumed and the metabolic processes within the organism, since shellfish may convert one toxin to another. A full discussion of this molluscan conversion process is beyond the scope of this study, but a detailed description can be found in Sullivan et al. (1983). Thus, PSP is caused by a "suite" of toxins present in shellfish. The syndrome is characterized in its most severe form by paralysis of the breathing muscles, which if left untreated by competent medical intervention, ultimately leads to death. In cases of paralysis, mechanical ventilation is highly effective. However, at lower doses, symptoms can range from mild stomach upset to a tingling sensation in the lips.

Alcoholic Versus Acidic Extraction Methods for PSP Toxins

In 1937, Sommer and colleagues established the connection between toxic shellfish and blooms of the dinoflagellate *Alexandrium catenella* (then known as *Gonyaulax catenella*) along the California coast. Sommer and Meyer (1937), in the course of their monumental study on PSP toxins, developed two extraction methods in their attempts of quantifying the amount of toxin present in shellfish. Their preferred method used acidified alcohol for the extraction of the toxin. Due to the laborious nature of this method, they developed a second more practical "field test" that used diluted hydrochloric acid and boiling for extraction. This field assay also used mice for the quantification of PSP toxins. Whereas the alcoholic extraction has been largely forgotten, the simplified field test (which was only minimally described) is still used today, with minor modifications, as part of the risk management of PSP throughout the world. Because the chemical structure and properties of the shellfish toxins were unknown in the 1930s and the purity of the extracts were also unknown, Sommer and Meyer's field test required them to define toxicity in terms of a Mouse Unit (MU) to quantify toxic activity. In their original work, Sommer and Meyer defined the mouse unit as the amount of toxin that killed a 20 g mouse within 10 to 20 min.

Sommer and Meyer's field method of extraction called for the

homogenization of 100 g of shellfish with 100 mL of 0.1 N hydrochloric acid, boiling this mixture, adjusting the final volume to 200 mL, and then filtering the mixture. Testing for toxin required the intraperitoneal injection of 1.0 mL of the filtrate into a mouse and then observing how long it took the mouse to die; therefore, an injection that killed a mouse in 15 min contained, by definition, 1 MU, and the total toxin content of the original 200 mL extract was 1.0 MU/mL \times 200 mL of extract or 200 MU. Because this extract was obtained from 100 g of shellfish meats, the shellfish were said to contain 200 MU per 100 g of shellfish.

Purification of STX From Shellfish

This unit of measuring PSP toxins was used up until the 1950s when a purified toxin standard became available from the US Food and Drug Administration (FDA). In the late 1940s and 1950s, researchers at Fort Dietrich isolated and purified saxitoxin (STX), the principal toxic component of PSP. Whereas initially intended for chemical warfare purposes, the unused portion of STX was eventually released to the FDA and became a shellfish standard. An official method that used this standard as a reference was accepted by the AOAC in 1959 (McFarren 1959). To use this standard as a control in bioassays, it was necessary to establish a relationship with the MU. Through experimentation, it was found that one MU was equal to approximately 0.2 μ g of the purified FDA standard, although variability between mouse strains ranged from 0.17 μ g to 0.28 μ g (J. Wekell unpub data). Because of this variation between strains, laboratories performing the mouse bioassay must "calibrate" their particular mouse strain against this toxin standard.

Calibration of the Mouse Unit

When the FDA accepted the use of the standard, they also accepted that 0.2 μ g STX equiv. = 1 MU as a reasonable average for a conversion factor (CF). Therefore, 200 MU became equivalent to 40 μ g of the purified toxin. Because the 200 MU detection limit was established from a 100 g batch of shellfish, the detection limit was subsequently expressed as 40 μ g STX equiv./100 g of shellfish, which remains the value that is still used today. Most likely, if the detection limit were set today, it would be expressed as 0.4 μ g/g or 0.4 ppm. However, because virtually all of the literature and databases have used the " μ g/100 g" notation for more than 60 years, it continues to be used to this day.

The use of a purified toxin standard also permitted more consistent estimates of PSP in shellfish. Sommer and Meyer developed a curve plotting MU and "death-times" (Fig. 1A). The curve in Figure 1 inset was derived from data in the report by McFarren (1959) and is currently used by regulatory agencies (AOAC 2002). Examining the death time curve, it is clear that very fast death times (e.g., less than ~5 min) can lead to very large errors in obtaining the correct number of MU. For this reason, the current regulatory method requires dilutions of the sample to bring the death times of the mice within 5 to 7 min, an area where the curve has a very minimal slope and time can be measured with reasonable precision and also permit good interpolation from the curve (Fig. 1B). From the curve and assuming a mouse correction factor of 0.2 we can derive the following: mice dying sooner than 5 min would exceed the regulatory limit of 80 μ g/100 g. Death times greater than 15 min place the concentration of PSP toxins at 40 μ g/100 g, approximately the accepted detection limit of the mouse bioassay. Therefore, using the mouse bioassay a regulatory labo-

Figure 1. Death times plotted against mouse units (A) and the suggested working range for the mouse bioassay (inset, B). Data from McFarren (1959) and AOAC (2002).

ratory can know in less than 10 min of injection whether dangerous levels of toxin are present in the shellfish.

New Chemical Techniques for Characterizing the Structure of Toxins

Within the past 30 years new chemical techniques such as high performance liquid chromatography (HPLC), x-ray crystallography, and nuclear magnetic resonance spectroscopy (NMR) have permitted the elucidation of the structure of the PSP toxins. The predominant toxin was named saxitoxin after the origin of the initial toxin source, the Alaska butter clam (*Saxidomus giganteus*). A trace component in the FDA standard was later found to be a close chemically related structure and was named neosaxitoxin. Using the techniques listed earlier, further research revealed that PSP poison found in shellfish consists not only of saxitoxin and neosaxitoxin but also a suite of closely related toxins that are commonly referred to as "gonyautoxins" (named after the original genus of the dinoflagellate that produces the toxins). Subsequent studies have shown that not all of these related toxins are equally toxic to mice or humans; some are more toxic than others. Because there is only the one toxin standard, predominantly saxitoxin, the resulting collective concentration of toxins in shellfish extracts are referred to as "X μ g saxitoxin equivalents/100 g shellfish"; sometimes abbreviated as " μ g STX equiv/100 g".

Establishment of the Regulatory Limit (80 μ g STX Equiv. 100 g⁻¹ Shellfish)

How the specific 80 μ g 100 g⁻¹ regulatory level was arrived at is open to some conjecture and the details are now, after over 60 years, probably lost to history. Prior to the establishment of the acid extraction method (only briefly described in Sommer & Meyer 1937) as the standard for regulatory purposes, California instituted quarantine measures when 2 mg of dried alcoholic extract contained 2 MU (Medcof et al. 1947). Tests at the Laboratory of Hygiene have shown this 2 mg to be equivalent to a toxicity of 400 MU per 100 g of whole meats, which is 80 μ g 100 g⁻¹ in today's parlance (Medcof et al. 1947). Canada also adopted the California standard of 400 MU as the quarantine level (Medcof et al. 1947).

Medcof et al. (1947) also examined epidemiologic records from

eastern Canada in the mid 1940s and found that in some cases a dose of 1,000 MU produced mild symptoms of PSP. Using the current conversion factor, 1,000 MU equals approximately 200 μg of STX equivalents, because the lowest dose reported for illness is 200 μg , and assuming that 100 g of shellfish meats might represent a reasonable quantity for an adult to consume, the lowest illness-producing concentration in shellfish would be 200 μg STX 100 g^{-1} . Based on these estimates and using a $\times 10$ safety margin, the regulatory level could be set at 20 μg 100 g^{-1} . However, this is well below the mouse bioassay detection limit. Therefore, the 80 μg 100 g^{-1} level was probably derived as a compromise based on the detection limit of the mouse bioassay (roughly 40 μg 100 g^{-1}) and yet still safely removed from the minimal toxicity of 200 μg 100 g^{-1} observed in the early studies.

Prudence and caution by risk management agencies over the years have maintained the regulatory level at 80 $\mu\text{g}/100$ g. This level seems to have weathered the "test of time" in that after 60 years of use the authors are not aware of a case of PSP reported in properly tested and released shellfish. Virtually all recent illnesses and deaths due to PSP are due to the recreational or subsistence victims ingesting untested shellfish or shellfish taken from quarantined or untested beach areas. In Alaska, because of the remoteness of the beaches and shoreline, the state has mandated that all beaches are quarantined to the taking of all shellfish unless otherwise specified by the state health authorities.

Regulatory Limit for Domoic Acid (20 μg DA/ g Tissue)

The Syndrome, ASP

Domoic acid (DA), the toxin responsible for amnesic shellfish poisoning (ASP), is a recent arrival to the list of known marine biotoxins and is naturally produced by some diatoms of the genus *Pseudo-nitzschia*. However, not all members of the *Pseudo-nitzschia* genus are highly toxigenic. The first reported ASP event occurred in Eastern Canada in 1987 when 4 people died and over 100 people suffered varying degrees of intoxication after consuming DA-contaminated mussels taken from Prince Edward Island (Todd 1990). Herbivorous fish were the vectors of DA in more recent intoxication episodes along the west coast of the United States in which dozens of sea birds and marine mammals died or were stricken with neurologic symptoms (Work et al. 1993, Lefebvre et al. 1999, Scholin et al. 2000). Fortunately, due to an extensive monitoring and surveillance program by the western coastal states (California, Oregon, Washington, and Arkansas) and the Province of British Columbia, no human cases of DA poisoning have been reported and officially confirmed since 1987.

Domoic acid is a low molecular weight, neuroexcitatory amino acid that can cross the blood-brain barrier and destroy neural brain cells. It attacks the glutamate signaling nerve system, destroying the cells that release the neurotransmitter glutamic acid (Debonnel et al. 1989, Berman & Murray 1997). Because regeneration of most brain cells is a relatively slow process, it appears that for practical purposes this damage is permanent and irreversible. In the known cases so far, elderly people seem to be more at risk than younger people (Todd 1993). In the Canadian outbreak, some people were institutionalized with permanent brain damage, while others have suffered varying degrees of short-term memory loss (Todd 1990, 1993, 1997). Follow up studies of the 1987 victims reported that some lost their businesses and the ability to conduct normal daily personal affairs. There is no known treatment for this intoxication.

Establishment of the Regulatory Limit for DA (20 μg DA/ g Tissue)

As in the case of PSP, arriving at a toxic dose of domoic acid in the 1987 episode was difficult because it was dependent largely on indirect measurements on recovered or uneaten products. Two important workshops that strived to set regulatory limits for DA were held immediately after significant DA outbreaks: The first was held in Ottawa, Canada from April 11 and 12, 1989 (Proceedings of a Symposium, Domoic Acid Toxicity, Can. Diseases Weekly Report, Vol. 16S1E, September 1990) and the other was held in San Pedro CA, February 6 to 8, 1992 (Domoic Acid Workshop, San Pedro, California, US Food and Drug Administration, San Francisco, CA, 1991). Lengthy discussions during these workshops illustrate the difficulty of arriving at the most rational regulatory levels that balance the protection of public safety with the economic provision of shellfish resources.

Because no documented and certified human illnesses were ever reported during the 1991 and 1992 United States west coast DA outbreak, all consumption and dose analyses were based on 1987 Canadian data. Recovery of uneaten mussels involved in that outbreak and subsequent analysis indicated that they contained levels ranging from 310 ppm to 1280 ppm domoic acid (Perl et al. 1990). Using these data, it was concluded that victims exhibiting mild and severe symptoms ate shellfish containing approximately 900 ppm DA and received a total maximum dose of between 200 to 300 mg (Wright et al. 1990). The lowest total dose that a minimally symptomatic victim received in the Canadian outbreak was reported to be about 50 mg (Iverson et al. 1989, Hynie et al. 1990, Iverson & Truelove 1994). Assuming a human adult of 70 kg, this translates into a toxicity range of 0.7 mg to 4 mg/kg, very close to animal oral toxicity levels in rats, mice, and monkeys (Iverson et al. 1990); however, mice and rats seem to be less sensitive than primates to the effects of DA. Using the lowest total dosage of 50 mg, assuming a consumption of 200 g shellfish meats, and a safety factor of approximately 12, it was concluded that the regulatory limit should be set at 20 μg DA g^{-1} shellfish.

In 1992, at a Domoic Acid Workshop held in San Pedro, CA sponsored by the FDA, the toxicity data was reexamined by epidemiologists and toxicologists from Canada and the FDA. During the San Pedro workshop, it was suggested that consumption of certain shellfish might be higher than 100–200 g of meat, perhaps as high as 500–1000 g. Nevertheless, after an extended discussion that reviewed the Canadian data, it was concluded that setting the regulatory limit of 20 μg DA g^{-1} shellfish would provide sufficient safety margins that would account for the variability between individual responses and the amount of shellfish consumed.

SUMMARY

The regulatory limits for both ASP (20 μg DA \bullet g^{-1} shellfish) and PSP (80 μg STX equiv. \bullet 100 g^{-1} shellfish) toxins have not changed since they were first implemented. These safety levels seem to be successfully protecting the seafood-consuming public and since their establishment no human cases of ASP or PSP intoxication resulting from regulated commercial seafood have been reported. These levels were driven by the detection capabili-

¹The San Pedro Workshop publication by the Pacific Region FDA office in San Francisco is a compilation of transcriptions of the semi-formal talks and discussions of the participants. Other than minor editing of typed transcripts, no formal peer review of the presentations was made.

ties of the time and the necessity to be conservative in the face of sketchy epidemiologic and toxicologic data. However, the value of this work, done up to 60 years ago in the case of PSP, is exemplified by quite literally "standing the test of time". Those levels, set in the 1930s, are still used today with only minor modification to the assay method itself.

Of course all regulatory risk managers would like to reduce risk to zero, but they know that this is not possible in the real world.

INFORMATION FOR CONTRIBUTORS TO THE *JOURNAL OF SHELLFISH RESEARCH*

Original articles dealing with all aspects of shellfish research will be considered for publication. Manuscripts will be judged by the editors or other competent reviewers, or both, on the basis of originality, content, merit, clarity of presentation, and interpretations. Each article should be carefully prepared in the style followed in prior issues of the *Journal of Shellfish Research* before submission to the Editor. Papers published or to be published in other journals are not acceptable.

Title, Short Title, Key Words, Abstract: The title of the paper should be kept as short as possible. Please include a "short running title" of not more than 48 characters including spaces, and key words. Each manuscript must be accompanied by a concise, informative abstract, giving the main results of the research reported. The abstract will be published at the beginning of the article. No separate summary should be included.

Text: Manuscripts must be typed double-spaced throughout on one side of the paper, leaving ample margins, with the pages numbered consecutively. Scientific names of species should be underlined or in italics and, when first mentioned in the text, should be followed by the authority. Common and scientific names of organisms should be in accordance with American Fisheries Society Special Publications 16 and 17; *Common and Scientific Names of Aquatic Invertebrates from the United States and Canada: Mollusks and CSNAIUSC: Decapod Crustaceans*, or relevant publications for other geographic regions.

Abbreviations, Style, Numbers: Authors should follow the style recommended by the sixth edition (1994) of the *Council of Biology Editors [CBE] Style Manual*, distributed by the American Institute of Biological Sciences. All linear measurements, weights, and volumes should be given in metric units.

Tables: Tables, numbered in Arabic, should be on separate pages with a concise title at the top.

Illustrations: Line drawings should be in black ink or laser print and planned so that important details will be clear after reduction to page size or less. No drawing should be so large that it must be reduced to less than one third of its original size. Photographs and line drawings should be prepared so they can be reduced to a size no greater than 17.3 cm × 22.7 cm, and should be planned either to occupy the full width of 17.3 cm or the width of one column, 8.4 cm. Photographs should be glossy with good contrast and should be prepared so they can be reproduced without reduction. Originals of graphic materials (i.e., line drawings) are preferred and will be returned to the author. Each illustration should have the author's name, short paper title, and figure number on the back. Figure legends should be typed on separate sheets and numbered in Arabic.

Digital Figures: Authors may provide digital figures (they are not required); they must be accompanied by hardcopy figures of equal quality, which the printer will use for comparison and backup. If digital figures are supplied, please note the following instructions:

- Each piece of art should be saved as its own file.
- Files must be one of the following formats: TIF, EPS, or JPG.
- Each file should be named according to its figure number and format (e.g., "fig2b.tif").

- Figures must not be embedded in a word-processor or spreadsheet document: the printer cannot use images stored in Word, WordPerfect, Excel, Powerpoint, etc.

- Resolution: *line shots*: 1000 dpi; *halftones/grayscale*: 300 dpi if no lettering, 500 dpi if figure contains lettering.

- Color figures: save the files as CMYK-encoded TIF images (preferred) or CMYK-encoded EPS or JPG images. Color figures have the same resolution requirements a B/W, above.

Color illustrations will not be accepted unless the author agrees to cover the cost of associated reproduction and printing.

Literature Cited: References should be listed alphabetically at the end of the article. Abbreviations in this section should be those recommended in the *American Standard for Periodical Title Abbreviations*, available through the American National Standard Institute, 1430 Broadway, New York, NY 10018. For appropriate citation format, see examples below:

Page Charges: Authors or their institutions will be charged \$100.00 per printed page. All page charges are subject to change without notice. A handling fee of \$50 will be charged for all manuscripts accepted for publication.

Proofs: Page proofs are sent to the corresponding author and must be corrected and returned within seven days. Alterations other than corrections of printer's errors may be charged to the author(s).

Reprints: Reprints and PDF files of published papers are available at cost to the authors. Information regarding ordering will be available from The Sheridan Press at the time of printing.

Cover Photographs: Appropriate photographs may be submitted for consideration for use on the cover of the *Journal of Shellfish Research*. Black and white photographs and color illustrations will be considered.

Corresponding: An original and two copies and electronic copy of each manuscript submitted for publication consideration should be sent to the Editor, Dr. Sandra E. Shumway, Department of Marine Sciences, University of Connecticut, 1080 Shennecossett Rd., Groton, CT 06340. E-mail: sandra.shumway@uconn.edu or sandrashumway@hotmail.com

Membership information may be obtained from the Editor or the Treasurer using the form in the *Journal*. Institutional subscribers should send requests to: *Journal of Shellfish Research*, P.O. Box 465, Hanover, PA 17331.

THE NATIONAL SHELLFISHERIES ASSOCIATION

The National Shellfisheries Association (NSA) is an international organization of scientists, management officials and members of industry that is deeply concerned and dedicated to the formulation of ideas and promotion of knowledge pertinent to the biology, ecology, production, economics and management of shellfish resources. The Association has a membership of more than 1000 from all parts of the USA, Canada and 18 other nations; the Association strongly encourages graduate students' membership and participation.

WHAT DOES IT DO?

- Sponsors an annual scientific conference.
- Publishes the peer-reviewed *Journal of Shellfish Research*.
- Produces a Quarterly Newsletter.
- Interacts with other associations and industry.

WHAT CAN IT DO FOR YOU?

- You will meet kindred scientists, managers and industry officials at annual meetings.
- You will get peer review through presentation of papers at the annual meeting.
- If you are young, you will benefit from the experience of your elders.
- If you are an elder, you will be rejuvenated by the fresh ideas of youth.
- If you are a student, you will make useful contacts for your job search.
- If you are a potential employer, you will meet promising young people.
- You will receive a scientific journal containing important research articles.
- You will receive a Quarterly Newsletter providing information on the Association and its activities, a book review section, information on other societies and their meetings, a job placement section, etc.

HOW TO JOIN

- Fill out and mail a copy of the application blank below. The dues are 75 US \$ per year (\$35 for students) and that includes the *Journal* and the Newsletter!

PREFACE

The 5th International Symposium on Abalone Biology, Fisheries and Culture was held at the Ocean University of China, Qingdao, China, from October 12–17, 2003. The original intention was to hold the symposium in April of 2003 but, because of worries about the SARS epidemic, the event was postponed for about 6 months, until the major concerns about the epidemic had passed. Despite some lingering apprehension, the conference attracted almost 300 delegates from 20 different countries, including representatives from the Americas, Africa, Asia, Oceania, and Europe. This Special Issue of the *Journal of Shellfish Research* contains many of the contributions presented at the conference.

The tradition of holding international abalone symposia started in La Paz, Mexico in 1989. At that time, symposia were held at roughly three-year intervals, in Hobart (Tasmania), Monterey (California), Cape Town (South Africa) and Qingdao (China). All of these symposia were extremely successful, and the number of people attending has gradually increased. Judging from the extensive list of delegates attending the Qingdao symposium, it is obvious that interest in abalone biology, fisheries, and aquaculture is still increasing.

The prominence of abalone in international seafood trade is well known. The astronomical prices paid for it, in certain international markets, is legendary. No wonder then, that abalone aquaculture production is rapidly increasing. The downside, however, is that worldwide fisheries are generally declining, not least because of the fact that the international illegal trade is still unac-

ceptably high. Despite regular calls to governments for actions to be taken against the illegal traders, poaching is still bringing some abalone populations to the verge of extinction. It is partly through the highlighting of this situation, through international symposia, that the plight of the world's abalone populations can be brought to the attention of politicians, hopefully encouraging them to take action.

The Qingdao symposium provided a platform for the presentation of well over 100 oral presentations and about 60 posters. Topics ranged widely and included international production and marketing; genetics; physiology and molecular biology; nutrition; diseases, fisheries and ecology; and aquaculture methodologies. This volume contains a selection of papers from each section, and all papers have been through the usual rigorous refereeing and review procedures of the journal. I wish to thank all authors who submitted manuscripts for publication and, in addition, I wish to thank the numerous referees who volunteered their time to review the papers. In particular, it is a pleasure to see the many papers that were submitted by Chinese authors for whom translation into English is often an additional burden to the presentation of their science.

The 6th International Abalone Symposium will be held in Chile in 2006.

WORLD ABALONE FISHERIES AND AQUACULTURE UPDATE: SUPPLY AND MARKET DYNAMICS

H. ROY GORDON¹* AND PETER A. COOK²

¹*Fishtech Inc., Box 6886, San Rafael, California 94903;* ²*Center of Excellence in National Resource Management, University of Western Australia, Albany, 6330, Australia*

ABSTRACT Culminating in the year 2002, a global shift in both abalone availability and distribution occurred. Country by country abalone reporting by FAO for both wild caught and cultured abalone changes significantly when further dissected and standardized. The FAO practice of reporting totals for “abalone shucked or not” and the continuing practice of some countries that still report their production by large groups of species, distorts both historical and current totals. Further review shows that the overall world supply of abalone, as a result of continuing increases in cultured production, combined with an unfortunate continued increase in the illegal wild catch is approaching the historical abalone abundance of the mid 1970s. However, major shifts have occurred when these dynamic changes are analyzed. These significant shifts demand inventive thinking on the supply side if prices are to remain at strong levels. Examples are given of approaches employing new creativity in the world of abalone marketing, distribution, and processing.

KEY WORDS: abalone, abalone supply, abalone fisheries, cultured abalone, abalone prices, abalone marketing

INTRODUCTION

An understanding of the dynamic changes in the world's abalone supply requires a comparison of the decade of the 1970s with the most current year: 2002. The abalone world of the 1970s was one with minimal regulation of the fisheries sector, little illegal catch, and a cultured “market size” industry measuring production in kilograms, not tons. In sharp contrast is the year 2002: 2 major abalone fishery countries (United States and South Africa) have either closed the fishery entirely or have threatened closure. During this same 3-y period the illegal catch has run rampant to the point where it now approaches 40% of the total legal fisheries. Nonetheless, much of the fisheries shortfall continues to be replaced through abalone farming. These factors lead us to the conclusion that the world's supply of abalone (fisheries, cultured, and illegal catch) in 2002 exceeded what was considered the “heyday” of world abalone supply during the 1970s. This surprising return to substantial supply quantities (in which the illegal catch plays no small role) suggests that substantial brand identification, specialty processing, and other marketing efforts/innovations are needed.

As a background reference, the following definitions are repeated (Gordon & Cook 2000):

Abalone fisheries: The total allowable annual commercial landing quota (country by country). This category includes the planting of seeds in large areas of the sea wherein the sea bottom has not been prepared with man placed rocks or structures. This definition does not include the legal sport catch or any illegal catch worldwide.

Cultured abalone: Includes both the farming of abalone on land or sea—contained in man made tanks, nets or structures (intensive culture), and in-sea planting of abalone seeds in artificially arranged substrate or structures, with or without adding food (extensive culture).

Illegal catch: Any world harvest of abalone beyond the total allowable annual landing quotas.

ABALONE FISHERIES

It is well known that over fishing, disease, habitat loss, and failed governing body management of the illegal catch have all

contributed to the decline of the abalone fisheries catch over the past 3 decades. There has been improvement in all but one of these factors (the illegal catch). Figure 1 illustrates country by country fisheries landings for the year 2002 as compared with low to high range averages for abalone fishery countries in the decade following 1970 (FAO historical data 1970/1980)

THE ILLEGAL CATCH

Certainly there was some illegal catch of abalone 2–3 decades ago; however it pales in comparison with the massive illegal take from the late 1990s to the present. Despite a myriad of laws and penalties in many countries, the illegal catch continued in 2002 at an unprecedented pace (Fig. 2). The relationship of the market price to ease of capture created a criminal market (in major producing countries they are well organized, well financed, and often armed). The entire United States abalone fishery was closed indefinitely in 1997, yet the illegal catch continues at over 120 mt per year (California Department of Fish and Game 2002). South Africa's law-enforcement authorities have been engaged in an armed battle to stop that country's illegal catch for a number of years. South African police (SAPS) 6-mo figures show 431 arrests between August 2002 and January 2003, with the admission that even with this strong effort “a lot of abalone are getting past us” (Groenewald 2003). For the year 2003, the SA Fisheries Department considered closing down any form of abalone harvesting once current rights expired. It was estimated that if poaching continued at the current rate, abalone would be fished to extinction in less than 3 y (Duvénhage 2002). The situation is so acute that for the year 2002 the illegal catch was estimated at more than double the 350 mt landings of authorized permit holders. (Tarr 2002).

The illegal catch in other abalone producing nations is substantial with deep-felt concern in Australia, Mexico, New Zealand, and Japan. There is also a notable illegal catch in other abalone fisheries (Korea, Philippines, Taiwan, and other Indo-Pacific countries).

CULTURED ABALONE PRODUCTION

Figure 3 illustrates the total cultured production as reported within each country (see Acknowledgments). The phenomenal growth of the world cultured abalone is evident when comparing the 8,696 mt for the year 2002 with just 689 mt 15 y earlier (as

*Corresponding author. E-mail: pacook@agric.wa.gov.au

Figure 1. World fisheries abalone landings (Illegal catch not included).

reported the first International Symposium on Abalone Biology, Fisheries and Culture, La Paz Mexico November 1989). Worldwide, more than 15 species are now being commercially cultivated with over 1,000 individual farms with individual production ranging from less than a ton to over 200 mt.

WORLD SUPPLY OF ABALONE FROM ALL SOURCES

In Figure 4 we compare the 2002 worldwide total of abalone from all sources (fisheries landings, illegal catch, and cultured production) with the abundant supplies of the 1970s; we find a near parity. There are however some substantial species differences: most notably lesser quantities of *H. rufescens*, *H. fulgens*, and exceptionally large quantities *H. diversicolor supertexta*, and to a lesser extent, *H. asinina*, and *H. ovina* (Nie 2002)

INDUSTRY CHOICE—GENERIC SELLING OR MARKETING?

Figure 5 represents a rather typical newspaper advertisement (in this case a “supermarket” in Hong Kong). Referring to footnote numbers we have superimposed onto the ad: “1” is frozen abalone from South Africa and “6” Frozen Green Lip from Australia. The ad merely sells frozen abalone from South Africa and Australia at the same price; there is no description of location within the country; there are no brand names, and no reference as to the quality of the supplier’s preparation process. Because some older buyers have biases as to one species or another, others would pay more for further guidance other than country of origin and “frozen”. The Supermarket’s suppliers by default become “generic” (i.e., the sellers to the supermarket were merely selling frozen abalone) with

Figure 2. World illegal abalone catch.

Figure 3. 2002 world cultured abalone production.

little attempt at well deserved and meaningful individual supplier or cooperative supplier marketing effort.

Contrast this with the marketing effort (Fig. 6) showing the cover of a processors brochure with brand name directly appealing to Asian markets. Inside the brochure are references to the specific waters and other perceived advantages of purchasing this brand name whether fresh, frozen, or canned. This strategy will, over time, result in continuing higher profits for this processor.

Figure 5 also identifies: “2” New Zealand canned, “4” CalMex brand from Mexico, and “5” canned from Australia. Canned abalone of necessity have some “brand” name on the can label as is the case “2” and “5”, however the price of “2” and “5” are in the same range, whereas CalMex “4”, with only slightly higher net weight commands, nearly double the price—an example of strong brand name marketing and recognition.

There is further marketing opportunity in specialty processing/preparation of abalone in any of its various forms. Figure 7 dis-

Figure 4. World supply of abalone from all sources.

Figure 5. Newspaper advertisement De Chang Food Market, Hong Kong.

plays the cover of a holiday food catalog (very big business in Japan) and a selection picturing abalone as a mixed, prepackaged presentation along with other seafood items. The price-to-weight ratio of this style marketing is astounding.

In addition to branding and other meaningful promotion, fresh marketing approaches to newly created specialty markets can yield substantial rewards to the abalone supplier and processor. One of Fishtech's Australian Clients is currently supplying a unique frozen processed product to Asia, transforming "generic" abalone into a much higher margin product.

ABALONE PRICING

In 1989 the United States was one of a very few substantial cultured abalone producers outside of Asia. The average prices

received by US farmers for this "little known" product in the year 1989 was in the \$30/36 kg C&F range (actual bids/ Japan 1989). In the year 2002 the same price range of \$30/36kg C&F was received by cultured producers for live product; notwithstanding worldwide awareness of the high quality, excellent taste, and consistent supply. Although there is no legal fisheries product available today from the United States and Canada, similar pricing scenarios can be developed for live product in the fisheries sector, with beach prices in the late 1980s in the United States and Canada no more than equating to today's prices on an inflation adjusted basis.

Similarly, Prices received by the fisheries and cultured producers in South Africa and Australia, were in the US \$30/36kg C&F range in 1998 (adjusted for live product) with little or no change in the 2002 prices received (Sunee 2002).

The downturn in some Asian economies and, in particular Ja-

Figure 6. Fisheries branding example.

pan. has certainly played a role in this downward price pressure; however a powerful factor has been the huge illegal fisheries sales into the world marketplace.

CONCLUSIONS

The abalone industry is currently suffering from the proliferation of the illegal catch. Unless governmental enforcement is substantially increased, the continued taking of these often immature animals will irreparably endanger the resource. This illegal catch also applies an important downward pressure on abalone prices because these abalone are most often sold in "peculiar" channels at well under commercial market prices. The slow recovering economy in parts of Asia also plays a role in suppressing prices. Nevertheless, whether considering the fisheries or the cultured industry, abalone in most all of its forms remains considerably under priced for this "shellfish caviar" product. The time has long

since come for those willing to put forth the effort to fully understand the current and new distribution chains (in particular China) and specific target distributors, wholesalers, and mega end users (DWEs). Next comes needed effort in processing and branding with realistic product marketing programs, both on an individual company basis and through "yet to be developed" abalone marketing co-operatives.

THE STATUS OF ABALONE CULTURE IN CHINA

ZONGQING NIE* AND SUPING WANG

Fuzhou Fisheries Research Institute, 3 Gule Rd., Fuzhou 350005 People's Republic of China

ABSTRACT Since 1990 abalone culture has spread widely from north to south on China's coast. Estimated total yield for the year 2001 was around 4,500 tonnes (excluding Taiwan). There are several hundreds of abalone farms along the coast. Some of the bigger farms produce more than 100 t of live abalone each year. The main cultured species are *Haliotis diversicolor aquatilis* Reeve in the south and *H. discus hannai* Ino in the north. Additionally *H. discus discus* Reeve has been introduced from Japan and hybridized with *H. discus hannai*. Crossbreeding has been applied in production. Tank culture and floating raft methods are important in the south and north respectively. At present, epidemic virus diseases and *Vibrio* are the gravest threat. Farms have suffered heavy economic losses as a result of these.

KEY WORDS: abalone, culture, China

INTRODUCTION

Since the previous review of abalone culture in China, written for the 1989 First International Symposium on Abalone Biology, Fisheries and Culture (Nie 1992) there has been dramatic change. Abalone culture in a mass scale in China began in the mid 1980s. It developed rapidly in the 1990s spreading along the coasts from north to south. Estimated abalone output was about 4,500 tonnes (excluding Taiwan) in 2001, 99% produced by cultivation. *Haliotis diversicolor aquatilis* (i.e., *H. diversicolor supertexta*) was around 65% of the total yield. The cultured species are varied. The technique of crossbreeding has been used widely (Nie et al. 1995a, Nie & Wang 2000). Triploid breeding has already started in production situations (Wang et al. 1990, Sun et al. 1993, Sun et al. 1998, Zhang et al. 1998). Because the abalone industry has developed rapidly sales prices have declined sharply. This has been especially so for the price of small abalone. For example *H. diversicolor aquatilis* sales price has been sometimes less than the cost of production. Epidemic diseases have occurred frequently since 1993 (Liu et al. 1995, Nie et al. 1995a, Ma et al. 1996). In particular a virus disease has appeared successively during late winter in the south since 1999 (Huang et al. 1999). Farms have suffered heavy losses and the virus is a serious threat for abalone culture at present.

Cultured Species and Distribution

There are eight species of abalone along China's coasts. Geographically *H. discus hannai* Ino is the only species in Liaoning and Shandong Provinces in northern China. The other seven species are distributed in Fujian, Taiwan, Guangdong, and Hainan, the southern provinces. These species are *H. diversicolor diversicolor* Reeve, *H. diversicolor aquatilis* Reeve, *H. varia* Linnaeus, *H. planata* Sowerby, *H. ovina* Gmelin, *H. clathrata* Reeve, and *H. asiatica* Linnaeus (Lu 1978, Dai & Wu 1989). Because *H. diversicolor diversicolor* grows slowly, *H. diversicolor aquatilis* becomes very important. This species was introduced from Taiwan to the southern continental coasts in 1989 and is now raised widely there. Additionally *H. discus discus* Reeve was introduced from Japan in 1986, *H. discus hannai* Ino from Dalian in 1990 and their hybridized generation are raised in the mid and northern Fujian (Nie et al. 1995b). There are now several hundreds of abalone

farms in China. The largest produce more than 100 tonnes of live abalone per year.

Culture Methods

The culture methods used in China are quite varied. Because of the coastal and climatic conditions they are different in the north and south. Long line raft is an important method in the north. A length of 60–80 m of rope ties together plastic floating globes to support cages. There are two sorts of cage currently in use. A special cage for abalone culture consists of 6–12 tiers of 60-cm diameter plastic dishes. The entire assembly is covered with a net sealed with a zipper. The second type used is a scallop cage, of 8–12 tiers of 33-cm diameter. Most rafts are mixed culture with abalone and algal food, *Laminaria* or *Undaria*. Rafts are also used in some bays in the south where the wind and waves are weak. In these instances a plastic basket, the same as indoor tank culture baskets, is used instead of the other cages.

Tank culture on land is the main type in the south. Because of frequent typhoons the culture had to develop on land. Concrete tanks are used of around 30–50 cubic meters. A dark PVC basket of 40 cm × 30 cm × 13 cm is in common use, usually in a stack of 8–12 tiers arranged in rows in a tank. The baskets occupy 40–70% of the tank capacity (Nie & Wang 2000).

In the western Guangdong and Hainan Province, in recent years, small abalone are cultured in the intertidal zone. A type of cylindrical concrete case, 110 cm × 80–120 cm (h) with an iron rack and net inside, is set on a low intertidal zone (Cai & Huang 2000).

Rocky intertidal zones in the north are also used. Here growers build frames and cover with net as well as other types of cages (Zhang et al. 1994).

Breeding Techniques and Present Problems

There are some differences in breeding techniques. The methods in the north are similar to Japanese methods in many ways, and in the south the methods approximate those of Taiwan.

All hatcheries in the north maintain parent stock with elevated temperature (20°C) in winter and induce spawning in spring. This allows sufficient warm weather for growing larger seed (to >15 mm) before the coming winter. In contrast the small abalone can induce spawning naturally from May to December (main season is September to November) in the south. Nonetheless some farms in the south also maintain parent animals with elevated temperature in winter and induce spawning from April to June.

*Corresponding author.

The substrate for larval settlement in the north is a corrugated plastic plate (40 cm × 31 cm) held in racks. Variations appear in the southern farms. Most farms prefer a transparent plastic sheet (60 cm × 40 cm) frequently set up so that many plastic sheets are hung under a wooden bar. Other types of membrane (rather than racked) corrugated plates are also used (Nie & Wang 2000).

A method of spawning induction with UV light and water temperature alteration (3 C to 5 C) is current. In the north, the fertilized eggs are maintained to the post veliger stage and then put into a tank for settlement. In the south it is more common to place fertilized eggs directly in a settling tank, with no water exchange until larval settlement. From the viewpoint of mass production the latter is quite feasible because it saves a lot of labor, time, and facilities.

The young juveniles are removed from the transparent plate/membrane at 2–4 mm, a much smaller size than during the early years of abalone culture in China. Commonly, in the north, the juveniles are then transferred in a box net with a dark plate on the net bottom. In the south they are raised directly on the bottom of another settling tank, on a substrate of square bricks with short legs that are arranged across the bottom of the settling tanks. The density of rearing is around 3,000–5,000 juveniles per square meter. A survival rate of about 40% to 60% is obtained and measured from the removal phase (2–4 mm) up to the end of nursery rearing (20 mm), in the south. A full cycle of nursery rearing takes about 6–8 mo with a mean production rate in all settling tanks of 2,000–3,000 seed.m⁻².

Present Problems

In recent years the nursery rearing has not been as easy as in the earlier years of abalone culture in China. On one hand large quantities of postlarvae after settlement (<20 days) fall off the substrate and die. On the other hand lots of young juveniles die when they are removed from substrate to horizontal rearing—usually within 15 days or so. These problems occur in the north and south, resulting in a requirement for more frequent spawning. Since 1995, in the north, a crossbreeding of local *H. discus hannai* with the same species introduced from Japan has generated improvements in this phase of culture. Unfortunately the improvements were not sustained for any longer than 2–3 y (Wang Q., pers. com. 2001) and for this reason some have believed that the species has degenerated by inbreeding after a long term of artificial culture.

Grow-out, Density, Cycle, Output and Market Size

In the north, a special cage for abalone culture is used with 400–600 seed (at >15 mm) per tier at the start of the grow out cycle. These animals are then scattered into other cages to reduce stocking density four times in the 2–3 y of the culture cycle. When they reach size classes of >55 mm and 75 mm they are sold to domestic and overseas markets respectively. For this phase the rafts used hang 25–30 stacks and a stack of 12 tiers crops 25–30 kg of market size abalone (Wang Q., pers. 2001).

In the south, a plastic basket is used in tank culture for 30–35 individual animals of 20-mm shell length. They are then grown in this basket to market size. Some farms raise 50 individuals in this basket at the start and then scatter them to give 30 individuals when they reach 30-mm shell length. A cycle from 20 mm to >50 mm takes about 6–8 mo. At present the small abalone are consumed at 90 individuals per kg (about 47 mm shell length) in the southern markets. A basket crops 400 g in this 6–8 mo. Per cubic

meter of water capacity there are 24–30 baskets, cropping 9–12 kg. Mean survival is about 75% (Nie & Wang 2000, Nie & Wang 2001).

The concrete cages used in the south for intertidal culture raise 500–700 juveniles at 10–20 mm shell length and harvest 6–7.5 kg in around 9–12 mo. The survival rate is about 50% to 60% (Qiu C.W., pers. comm. 2001).

Food

China is a country in which abundant culture, of algae such as *Laminaria japonica* and *Undaria pinnatifida* occurs. Natural resources of *Gracilaria tenuistipitata* abound in the south. The brown and red algae are favorites of *H. discus hannai* and *H. diversicolour aquatilis* respectively. The feeding habit of the latter is wide ranging. Its growth rate when fed on dry or salted *Laminaria* is faster than when fed on the fresh *Gracilaria* (Nie et al. 2000). Additionally *Encheuma gelatiniae*, raised in Hainan, is also supplied for abalone food.

Artificial feeds for the nursery stage are very popular in China. There are powders and different sizes of granules. A few farms have fed on flat feed for the nursery stage. The growth rates of abalone, fed on artificial diets, are faster than the growth rates of those fed on algae (Nie et al. 1986, Nie et al. 2000).

Disease

Main Diseases and Enemies

Bacteria: Bacterial disease, especially *Vibrio* is common in aquaculture. An epidemic disease of abalone occurred first in Dalian, northern China in 1993. It is called "pustule disease". The pathogens are *V. fluvialis* and *V. campbellii* (Nie et al. 1995a, Ma et al. 1996). The outbreak that summer caused the loss of 60 tonnes of adult abalone ($\sim 5\text{cm}$ – 8cm). Following that event the epidemic diseases caused by *V. vulnificus*, *V. alginolyticus*, and *V. metchnikovii* were successively identified in Fujian and Guangdong (Nie & Wang 2000) (Figs. 1, 2, 3). Additionally a *Flexibacter* spp. disease has occurred in Guangdong (unpublished data). All are capable of causing high mortality in some situations.

Virus: So far the most serious disease caused by a virus epidemic occurred in the spring of 1999 in Dongshan County, the south of Fujian. It caused 100% mortality at 22 farms within 43 days. A globular virus of dimension $5\text{--}80 \times 120\text{--}150\text{ nm}$ was identified (Huang et al. 1999) (Fig. 4). In the early winter from 1999 to 2002, at about $21\text{ }^{\circ}\text{C}$ water temperature, it reappeared at Dongshan and spread to Guangdong. Many farms were infected.

Figure 4. Micrograph of the bladder coat of the virus in the digestive gland of *H. diversicolor aquatilis*. ($\times 40,000$) (courtesy Y.Y. Huang et al. 1999)

Figure 5. Abalone, *H. diversicolor aquatilis*, secreted naere around its conical appendage due to the settlement of *Polydora*.

Those farms that were infected could not escape another outbreak the next winter (unpublished data). It is clearly a terrible disease for abalone. The clinical signs include: tank water turbid and bubbly because of vomit; after death an atrophied and dark foot muscle still settles on the wall (or basket) of the tank (Huang et al. 1999).

Polychaeta: *Polydora* spp. occurs in the shell of abalone at some farms in the south. They live on the surface of the inside of the shell or in a cave in the rear ventral edge of a shell. The abalone secretes naere in an attempt to form shell to resist the worms harassment (Fig. 5). The infected abalone becomes very lean and death finally occurs. The smallest infected abalone found was 17-mm shell length *H. diversicolor aquatilis*. This animal had a cave of the worm, 12-mm in length (Nie & Wang 2000). Another clinical sign associated with *Polydora* is rupturing of the mantle at the point of the visceral mass (unpublished data) (Fig. 6). This is called "ruptured abdominal disease." An infection of *Polydora* also caused high mortality at some farms. It is possible that the high mortality occurred as a result of an infection with *Vibrio* synchronously.

In addition to the above diseases, notable but occasional attacks of parasitic protozoans such as *Sporozoa* (unpublished data) (Figs.

Figure 6. Rupture of the mantle (\uparrow) at the point of the visceral mass due to the settlement of *Polydora*, and borings of *Polydora* (\uparrow).

Figure 7. Micrograph of tissue of the digestive gland of *H. diversicolor aquatilis* parasitized by amoeboid corpuscles. ($\times 400$)

7, 8), *ciliata* (Li et al. 1999) have occurred. Another virus disease called "crack shell" caused by a globular virus of 90–140 nm (Li et al. 1998) occurs occasionally.

Cure and Prevention

Some antibiotics such as chloramphenicol, furazolidone, ciprofloxacin and cotrimoxazole, and similar are effective for inhibition of bacteria in seawater. Among these the first 2 are the most effective, however, they are no longer allowed in China. They do not usually cause antimicrobial resistance, and they are both cheap (Nie & Wang 2000). In tank culture the animals are soaked and aerated continually in a 3–4 ppm solution of an equal mix of chloramphenicol and furazolidone for 4–6 h a day. A course of cure takes 3–5 days (Nie et al. 1995a, Nie & Wang 2000). In cases of very high mortality it can be treated twice a day (unpublished data). In most cases the deaths can be controlled. In addition to increasing the frequency of use of the drug, the dose can also be gradually increased. Some effects are obtained by combination of the above antibiotics with a bactericide, such as chlorine dioxide (ClO_2), sodium dichloroisocyanurate, and bromochlorodimethylhydanto all soaked simultaneously with the antibiotic (Nie & Wang 2000). To this date there is no way known to treat the *Polydora* and virus diseases.

Figure 8. Micrograph of tissue of the digestive gland presenting diffuse necrosis and merger infection by bacteroid pathogen and amoeboid corpuscles. ($\times 400$)

Consumers and Pricing

Most products are sold live in domestic markets. A few are consumed frozen and as dry food. The people of Guangdong are the highest consumers. Recently abalone are not only sold to restaurants but also to families. Large cities near the coasts have become the second largest consumers. Some *H. discus hannai* is exported to Japan and South Korea. Some live and canned abalone is also imported from Australia and South Africa. The price of small abalone has declined to US\$ ~10–25 kg^{-1} whereas *H. discus hannai* and *H. discus discus* are selling at around US\$ ~36–46 kg^{-1} .

Prospects

The development of abalone culture is expected to be slow in the future, with output remaining steady. In the north, the extensive cultivation by releasing seed on the sea bed will be increased under the "Law of Use and Administration of Sea Areas." Producers will be expected to pay more attention to the prevention and cure of disease and to breeding technology for improvement of culture quality and disease resistance.

ABALONE MARICULTURE IN CHINA

GUOFAN ZHANG,^{1*} HUAYONG QUE,¹ XIAO LIU,¹ AND HUASEN XU²

¹Institute of Oceanology, Chinese Academy of Sciences, Qingdao 266071, People's Republic of China;

²Zhanjiang Marine and Fishery Bureau, Zhanjiang 524074, People's Republic of China

ABSTRACT Remarkable progress has been made in recent years in abalone cultivation in China. Beginning in the early 1980s, commercial scale mariculture of abalone has involved 2 species: Pacific abalone, *Haliotis discus hannai* Ito and the small tropical abalone, *H. diversicolor* Reeve. Intensive culture of *H. d. hannai* is distributed mainly in the northern China region, Liaoning and Shandong Provinces with an annual production increasing from about 47 mt (1992) to 4500 mt (2003). The small tropical abalone is the dominant species with a total production of *H. diversicolor* reaching 3878 mt produced in 2001 in Fujian, Guangdong and Hainan Provinces. Seeds for cultivation are exclusively produced from hatcheries with well-developed technology. Cultivation practices may vary widely among different sea types. Three major forms of grow-out are used in abalone cultivation, land-based tanks, suspended longline cages and intertidal ponds. Abnormal mortality has threatened sustainable development of the abalone industry from its inception. During 1992 to 1996, many facilities in the north ran at a loss due to mass mortality occurring in juveniles and seeds. Mortality usually occurred in the postsettlement nursery phase when spat remain on settlement plates, characterized by cease of dietary intake and falling from the substratum. The cause of this large-scale mortality remains as yet unknown. The same situation occurred in Fujian from 1996, after 2 y of large-scale farming, and has already spread to all other provinces of abalone mariculture. Genetic improvement of abalone has drawn much attention. Hybridization between different populations from Japan and China has been achieved to obtain significant heterosis with growth and survival. Preliminary results on *H. d. hannai* have shown that survival of selective strains is significantly higher than normal controls.

KEY WORDS: Abalone, *Haliotis discus hannai* Ito, *H. diversicolor* Reeve, mariculture, seed production, grow-out, disease, abnormal mortality, hybridization, heterosis, selection breeding, marketing, China

INTRODUCTION

Six species of abalones are naturally distributed along the coast of China, *Haliotis discus hannai* Ito, *H. diversicolor* Reeve, *H. asinina* Linnaeus, *H. ovina* Gmelin, *H. planata* Sowery, *H. varia* Linnaeus, and *H. clathrata* Reeve (Nie 1992). Abalone aquaculture has been dominated by *H. discus hannai* and *H. diversicolor*, whereas culture of *H. asinina* has drawn considerable attention in recent years.

Experimental production of abalone seed in Pacific abalone was conducted in 1977 (Chen et al. 1977) in China, and commercial seed production was accomplished in 1987 in Dalian, Liaoning. From 1987 to 1992, abalone aquaculture in China grew steadily with most research focused on the development of hatchery seed production techniques and grow-out modes. A series of key techniques involving spawning, larval rearing, and juvenile and seed nursing were established. Grow-out systems including culture in suspended longline cages, land-based tanks, intertidal ponds, and tanks were also established.

From 1992 to 1996, however, abalone aquaculture suffered severely from disease in the northern provinces of China. Abnormal mortality of cultured abalone seed, *H. d. hannai*, was first observed in 1992. The mortality problem became evident after 1994, when most abalone hatcheries suffered severe loss of abalone seed, either larvae or juveniles. From 80% to 90% mortality has been reported. During this period, approximately 20% to 30% of 1–3-y-old cultured abalone suffered abnormal death. Meanwhile, wild abalone stocks also suffered mass mortality. Therefore, output of abalone in northern China decreased considerably during 1996 to 1998.

From 1997 aquaculture of *H. d. hannai* in northern China rejuvenated and entered a stage of rapid and stable development.

Success of abalone industry, in north China, resulted from improvement of seed production techniques and implementation of sanitary measures.

During the 1990s, commercial cultivation of the southern abalone, *H. diversicolor* emerged and then expanded rapidly in Southern China. The first trial of hatchery seed production was conducted in Shenzhen in 1992, following the procedure for *H. discus hannai* in the north. This trial, however, came to an unsuccessful end. A package of cultivation techniques was well developed in Taiwan province and popularized in southern provinces of China from 1994. Subsequently, seed production of *H. diversicolor* on a commercial scale expanded until 1998 and saw the rapid development of abalone farming in southern China. Mass mortality occurred initially in January 1999 in Dongshan, Fujian, and then in Shantou, Guangdong. Some companies lost all their abalone. The problem has now spread to Hainan and Guangxi. Most of the abalone hatcheries on the southern Chinese coast are now running limited operations or considering closing.

To summarize, intensive culture of *H. discus hannai* is mainly distributed in north China, with the majority of the production in Liaoning and Shandong. *H. diversicolor* is the dominant cultured species in south China. Abalone culture has become one of the most important components of molluscan mariculture in China. Abalone holds the top position in terms of commercial value among farmed molluscan products. Mariculture production of abalone increased steadily during the 1990s. Despite production of *H. diversicolor* undergoing a decline since 2000, total output of marketable abalone has continued to grow from 1997 onward. This growth is mainly attributable to the rapid increase in production volume of *H. d. hannai*.

In this study, development of large-scale cultivation of abalone, in association with technology, as well as marketing of abalone is reviewed. Meanwhile, problems arising from abalone mariculture and possible countermeasures are discussed herein.

*Corresponding author. E-mail: gfzhang@ms.qdio.ac.cn

SEED HATCHERY PRODUCTION

Sufficient seed supply is crucial to the development of abalone mariculture. All abalone seeds are hatchery produced with sophisticated technology. For *H. discus hannai*, seed production typically begins in early spring with broodstock conditioning at gradually elevated temperatures and stabilization at 20°C. The most widely used and effective method for abalone to ripen is by effective accumulative temperature (EAT) control. Experiments with Pacific abalone demonstrate that the required EAT is 800°C-day for males and 1000°C-day for females. Meanwhile, plenty of algal food, *Laminaria japonica*, *Undaria pinnatifida*, and *Ulva pertusa* should be provided with this conditioning method. However, conditioning at elevated temperatures is not effective for *H. diversicolor*. Alternately, conditioning is conducted for tropical abalone by lowering culture density to 10–15 individual/cage and adding supplements of fresh macroalgae.

To induce spawning, well-developed abalones are exposed to air for desiccation and then subjected to ultra-violet-irradiated seawater. Adult spawning is usually induced by combined thermal shock and UV-treated seawater exposure. Few hatcheries use hydrogen peroxide to induce spawning for *H. diversicolor*. Males usually are induced 1 h later than females because the former are more sensitive to inducement than the later. Fertilized eggs are incubated at 21°C to 22°C and 22°C to 30°C for the northern and southern types, respectively. Approximately 60 h postfertilization, *H. d. hannai* larvae are ready for settlement. Eyed larvae are set on the collecting plates made of transparent corrugated plastic with diatom-precoated for *H. d. hannai*. In southern China, plastic films (usually polythene with 0.2–0.3 mm thickness), which are precoated with diatoms, are widely used for *H. diversicolor* larval collection. Using plastic film has achieved satisfactory settlement percentage and postsettlement survival. However, this stage is critical and survival after settlement is the biggest challenge for abalone seed production. The diatoms must be supplied in sufficient quantities as well as in good quality to ensure the growth and survival of postlarvae. Water quality and light level should be carefully controlled during this critical period.

Juveniles are manually moved from settlement plates to nursery culture plates at approximate size of 3–7 mm. For *H. discus hannai*, spat are usually transferred to large punctured plastic plates with dark color. For *H. diversicolor*, however, spat are reared in concrete nursery tanks. Square cement plates, with feet on the four corners, are placed on the bottom of the tanks. During early juvenile stages, an artificial diet is exclusively used as food supply. Several commercial diets, from various diet producers, are available to aquaculturists. The major ingredient of artificial diets is dried kelp powder and fish meat powder. Fresh kelp is the principal food for older juveniles. The quality of artificial diet plays an important role in postsettlement survival.

GROW-OUT SYSTEMS

There are at least 3 major grow-out methods being used widely for abalone culture. First, grow-out in land-based tanks is a popular system, and the most intensive and sophisticated. The method is applicable to both the cultured species. In southern China, this method had developed in Taiwan before 1994. It has become the predominant culture method for the abalone culture industries in South China. The major husbandry measures include adequate feeding, control of water flow, periodic elimination of abalone waste, and adjustment of the culture density. Usually this grow-out

system has a high running cost, including cost for water pumping, heating, and aeration. For northern China, this grow-out system is applied less than in southern areas. One of the most successful facilities running this grow-out system is Xinda Products Co. located in Dalian, Liaoning, retaining stable full production for many years.

The second cultivation form is in cages or barrels on suspended longlines. This system was initially tried in north China in the late 1980s. For the southern coast, the first trial was conducted in Shenzhen, Guangdong, in 1992. Relatively fast growth at lower costs could be obtained with this abalone grow-out system. Therefore, this method has been widely adopted along the coast of China. Feeding with macro-algae is usually conducted weekly. The grow-out usually lasts for 8–13 mo for *H. diversicolor* on the south China coast.

The third form is culture in intertidal ponds. The seed of *H. diversicolor* is put into a cement tank, diameter 120 cm and height 60 cm, wall thickness 5 cm, with a cover and a rack for the abalone settlement. There are several poles in the cover, bottom, and wall for the water change between the inner and outer parts of tank; 500 to 700 seeds of 2 cm shell length can be placed in each tank. Tanks are set in the low intertidal or upper subtidal zone and fed with fresh algae once per week or more according to the weather, and the amount is 20% to 30% of the total weight of abalone in the tank. The grow-out of abalone usually takes an average of 7 mo, varying from 5 to 11 mo. This is a closed system and has first applied in Zhanjiang, Guangdong in 1993. From the unprecedented success of this culture mode in 1997, an upsurge in popularity occurred during 1998 to 2000. Since 2002, however, the practice has declined sharply due to abnormal mortality from early seed to adult. One reason is that rapid development of abalone farming has resulted in environmental disruption in coastal water and epidemic pathogens.

In northern China, intertidal farming emerged in 1998 when hybrid seeds were successfully produced and the over-wintering problem solved. Some cement ponds have been built in the low intertidal zone with an area 0.5–1.0 hectare, with stones placed in the pond for the settlement of abalone. Ponds are about 1–2 m(s) depth depending on the position and the system of water exchange. There is a net along the pond wall to prevent abalone escape. No tank was used in the north. The seed size is 2.0–2.5 cm shell length and 15–20 individual/m². The grow-out needs 16–20 mo to reach the size for market in Qingdao. Generally, there is an opening system for abalone grow-out, which has been developing quickly off the coast of Qingdao, Shandong. The ratio of marketable abalone produced from this grow-out system has steadily increased in recent years. In 2003, production of marketable abalone reached 2615 mt in the Qingdao area, accounting for over 58% of the total yearly output in Shandong. Grow-out management includes periodic feeding on macro-algae and removal of dead bodies. One disadvantage of this opening system in the intertidal zone is that it impedes natural beach scenery.

In addition to the above mentioned grow-out modes, abalone can also enhanced on the bottom of the subtidal zone. This has been used in a couple of coastal area, such as the Changhai County in Dalian, Liaoning.

During the grow-out period, abalone are fed primarily on the macroalgae, *Laminaria japonica*, *Undaria pinnatifida* or *Ulva pertusa* for *H. d. hannai* and *Gracilaria* sp. for *H. diversicolor*. Additionally, *Laminaria* and other macroalgae are used partially for *H. diversicolor*. During summer, following the completion of the

kelp harvest, kelp supply could be in short supply for 2–3 mo. Salted or cold-stored *Laminaria* substitutes for fresh kelp as the abalone food supply during supply problems of fresh food. Both salted and cold-stored *Laminaria* should be processed before use.

MARKETING OF MARICULTURE PRODUCTS

Aquaculture products of abalone are primarily sold fresh in domestic markets of China. Tinned products are available at some abalone farms. Most canned products were sold in the overseas market.

CHALLENGES TO ABALONE MARICULTURE

Mortality frequently occurs during the first month of the juvenile phase, following the movement of juveniles from settlement plates to the nursery culture plates, especially when the juveniles are taken-off the diatom plates at <5 mm shell length. It is generally believed that the change of feeding habits is the major cause of this high mortality. Survival in this critical nursery period has dropped to lower than 5% at the lowest level during the early 1990s. Survival of early juveniles has been much improved by hybridization breeding, declining juvenile density in the collecting plate, and extension of diatom feeding, therefore, allowing for removing the juveniles, at a larger size than normal, to the nursery culture plates (Zhao & Zhang 2000). In particular, hybridization was made between Japan and China's broodstock to produce hybrid seeds. When all diatoms on the settlement plate are consumed, juvenile abalone (approximately 2–3 mm) are transferred to another batch of transparent corrugated plastic plates on which diatoms are well covered. Therefore, size of juvenile abalone reached 5–7 mm when transferred to the nursery culture plate, enhancing the adaptive ability of juveniles to artificial diets. The practice of transferring juvenile abalone is now becoming part of routine hatchery procedure. With the application of hybridization and plate-transfer techniques, production of *H. d. hannai* remains stable in the northern Chinese coast areas.

This problem, however, was not solved completely due to incomplete understanding of the physiologic variation associated with the change of feeding habits, following larval metamorphosis. In addition, a lack of quality control, with respect to broodstock, often leads to failure of utilization of heterosis. Hybrid abalone seeds have now been widely adopted throughout the northern coasts. Nevertheless, breeding of high quality lines of abalone will be the best solution in terms of genetic modification.

Availability of adequate commercially formulated diets is another problem for the abalone aquaculture industry in China. Abalone is a slow feeder, therefore, reducing leaching of water-soluble ingredients from artificial diets would be key to good diets. Furthermore, dietary essentials should be balanced to meet the nutrient requirement of abalone. As yet, however, nutritional requirements of the cultured species have not been fully demonstrated.

RECENT ADVANCE AND PROSPECTS

With the development of abalone aquaculture, the demand for abalone lines that are genetically improved has become a common concern. To meet this urgent demand, the Ministry of Science and Technology of China has provided funding for genetic improvement and breeding of mass culture species (e.g., *H. d. hannai*).

Heterosis has been used extensively in Pacific abalone farming. Most seeds used for mariculture are hybrids of the Japanese and Chinese populations, all showing a significant heterosis in growth and survival with 17.98% in shell length, width 22.07%, total weight 61.93%, and survival 180% compared with the control. Heterosis is the foundation of a modern abalone breeding program. The selective strain study has made significant progress with a selective line obtained. This abalone has the characteristics of uniform size, fast-growth, and high survival in all developmental phases. The selection pressure in the first generation was conducted at 0.2%. Selection was undertaken for 2 successive generations and F₃ offspring have been obtained. This abalone line is a high-quality candidate for aquaculture and has the potential for promotion of the abalone culture industry in China.

To facilitate abalone breeding, marker assistance selection (MAS) based on molecular markers has been conducted in cultured abalone species. For example, the random amplified polymorphic DNA (RAPD) technique has been used to investigate genetic differences of the abalone, *H. d. hannai* in 4 progeny families from different geographical populations in China and Japan, as well as genetic variation between parent abalone (from Japan and China, respectively) and their hybrid offspring (Wan et al. 2001, Zhang et al. 2002). The construction of full length cDNA library of *H. d. hannai* lno from F₁ offspring of J₁R_b family had been fulfilled (Liu et al. 2004) and EST sequencing of the "Chinese Red" line of abalone (Liu et al. 2003) and genetic linkage mapping for high quality family in growth and survival are ongoing.

Chromosome manipulation has been conducted in both *H. d. hannai* (Wang & Zhang 1990) and *H. diversicolor* (Rong & Weng 1990). Triploids were induced with various methods including cold shock, treatment of cytochalasin B, or of 6-dimethylaminopurine (6-DAMP) in the abalone, *H. d. hannai* (Sun et al. 1993, Zhang et al. 1998). Unfortunately, no successful application of triploid abalone in mariculture has been reported until now.

High mortality occurring during abalone culture, either nursery or grow-out stage is another crucial issue for both abalone aquaculturists and researchers. Epidemiology investigation and pathogen identification are ongoing and progress has been made. Two major diseases have been reported in China. First, a fester disease has been reported in juvenile abalone. The pathogenic bacteria of the fester disease was verified as *Pseudomonas fluorescens* and some antibiotics, including Kanamycin, Oxolinic, and Furaxone have been found to be effective in curing this disease (Ye et al. 1997). An Elisa method for detecting the pathogenic bacteria of the fester disease in cultured juvenile abalone was reported (Ye et al. 1998). Second, a serious pustule disease was also found, usually in grown-out abalone, caused by *Vibrio fluvialis* (Liu et al. 1995). Various antifibrosis vaccines for cultured abalone *H. d. hannai* were examined. There is still a long way to go before mortality can be effectively controlled. The occurrence of inexplicable mortality will complicate abalone aquaculture for the near future.

ACKNOWLEDGMENT

The authors thank Dr. Huang Bo, Dr. Ke Caihuang, and Miss Lin Zhishu for providing valuable first-hand information on abalone mariculture of various provinces; and Miss Kirsty for her review in English. This study was financially supported by National High Tech R & D Plan (863 Plan), grant number 2001AA621070 and 2003AA603023.

STATUS OF THE ORMER (*HALIOTIS TUBERCULATA* L.) INDUSTRY IN EUROPE

S. M. H. HUCHETTE^{1,2,*} AND J. CLAVIER¹

¹LEMAR Laboratory, European Institute for Marine Studies, University of Western Brittany, France;

²Zoology Department, University of Melbourne, Victoria, 3052, Australia

ABSTRACT The ormer (*Haliotis tuberculata*) occurs from the Senegal coast in the south to the Cotentin peninsula of France in the north. Commercial fisheries currently operate in France and Spain. The French abalone fishery was opened in 1994. Abalone catches are regulated by a permit and quota system. Total Allowable Catch (TAC) was determined by two initial stock assessments carried out locally in the vicinity of St Malo, Central-North Brittany, and Morlaix, North-West Brittany, in the 1980s. Quotas have since been revised, according to decisions of local fishing committees, without information on the stock situation or independent assessments since the opening of the fishery. In 1996 to 1997, a severe bacterial disease devastated the stock of the main fishing grounds in St Malo and many other places around Brittany. Mass mortalities were correlated with high sea surface temperatures. The stocks have only partially recovered since then, and the total catch has been significantly reduced from about 80 tons to 60 tons per year, resulting in catches significantly lower than the TAC currently implemented. There are no reliable catch per unit effort data available. The absence of a strong enforcement policy, evidence of poaching, and strong activity of the local black market constitute a situation where there is a significant threat to the stocks and sustainability of the fishery. In Spain, the fishery was reopened in 2002, after 10 y of inactivity related to PSP toxins found during imports into the Japanese market. It was closed again, soon after reopening in 2002, because of a major oil spill on the Northern coasts. An abalone aquaculture industry is developing around Europe, mainly in Ireland where *H. discus hannai* and *H. tuberculata* have been imported and acclimatized. There are prospective aquaculture developments in France, England, Spain, and Scotland.

KEY WORDS: ormer fishery, France, *Haliotis tuberculata*, management, *Vibrio carchariae*.

INTRODUCTION

Considering the status of the abalone industry worldwide, with the high commercial value of the product and the collapse of many fisheries, it is likely that the remaining abalone stocks will be put under greater pressure (Gordon & Cook 2001). The reasons for stock collapses are varied, but they may be linked to over exploitation of the resources, unwise management, inadequate enforcement policies, or disease.

The ormer, *Haliotis tuberculata*, is the only European species that reaches a large enough size to be harvested. It occurs from the Senegal coast, in the south, to the Channel Islands in the north (Gaillard 1958, Mgaya 1995). It is traditionally fished in western France where it is considered a delicacy.

It was considered as a potential candidate for aquaculture development in the 1970s in France, where technical feasibility studies were conducted (Koike 1978, Flassch & Aveline 1984). At that time, however, these studies concluded that ormer culture was not economically viable due to its low market value (3–10 €/kg) and slow growth. Commercial fishing and mariculture interest of the ormer significantly increased all through Europe in the early 1990s following easier international commerce (rapid transport and globalization of markets) and an increase in its export values to Asia.

In this study, fisheries information was collected by direct investigation in the field, by interviewing professional fishermen and scientists, and from a review of the existing literature. We describe recent changes in the European industry and its current status, analyze management strategies, and discuss potential future developments.

DESCRIPTION OF THE INDUSTRY

Recreational Fishing (France)

The ormer has been fished in France for many years. Fishing restrictions have been established by regional fishing committees,

and are enforced by the Directorate of Maritime Affairs. Restrictions include a minimum shell length of 8 cm (until 1996 then 9 cm), a bag limit of 20, and a seasonal closure from June 15 to August 31. Recreational fishing can only be carried out on foot and the use of a fishing hook is allowed. No breathing apparatus, and no swimming is permitted, and the fisher's head must remain above water at all times. Fishing is carried out only during extreme low tides and is only allowed between sunrise and sunset. Fishing licenses are not required.

The major problem, however, is that few people are aware of these rules because they are not widely advertised on the assumption that "no one is supposed to ignore the law." Recreational fishing is not estimated, however there were 4,000 shore gatherers in the Rade of Brest in 1963 during the equinox tide, 2,000 in 1984 and 1,000–2,000 in 1996 (IFREMER statistics). Clavier (1992) estimated the total catch of these shore gatherers at about 20 tons each year.

Commercial Fishing (France)

Commercial fishing started in 1994 for a preliminary experimental period of 1 y. License holders are SCUBA divers, restricted to only 2 SCUBA tanks per day. Health and safety regulations for professional diving require three qualified divers (commercial diving certificates are required) on board the boat. Abalone, minimum shell length of 9 cm, can be collected with an abalone iron or hook. All abalone fished must be marked before landing with individual plastic seals (colored according to the fishing zone and marked with a personal seal). Five thousand individual plastic seals are given to the fishermen at the start of the season for each ton of quota. Management is funded by the cost of the annual commercial fishing licenses (€152.45/boat per year). A seasonal closure from June 15 to August 31 applies. The control and enforcement of these regulations are carried out upon arrival in the port. If, during a control operation:

- more than 20% of the fish caught are under the minimum legal size, the fishing license is cancelled for 1 y.

*Corresponding author. E-mail: sylvain.huchette@wanadoo.fr

- there are no seals on ormers during transport, the license is permanently removed.

Poaching seems wide-spread. It is likely that well-organized parallel networks supply local markets, Parisian restaurants, and illegal exportations. Prosecution of poachers is slow and less dissuasive than overseas: for example, 2 poachers were sentenced in 1999 to 6 mo in jail and fined €8000 for poaching 28 tons between 93 and 95 (Ouest-France, daily newspaper, September 1999).

There are 5 fishing zones in Northern Brittany and Normandy (Fig. 1 & Table 1). The French management system for abalone fisheries is presented in Figure 2 and is mainly carried out at the local level by Local Fishing Committees (LFC). Each local fishing committee has its own management strategy, with the Normandy one being more distinct than those in the four Brittany zones, because Normandy belongs to a different administrative region. In Normandy, the SMEL (Syndicat Mixte Pour l'Exploitation du Littoral, Blainville, Cotentin), a local research and development center funded by the French Departement of La Manche, works closely with the fishermen and IFREMER and provides management advice. In Brittany, IFREMER (Institut Français pour la Recherche et l'Exploitation de la Mer), is in charge of advising LFCs, but it takes a limited part in the decision process. There are no regular stock assessments carried out. As a result, the fishery is in an awkward situation where the quantities of abalone officially fished are well below the Total Allowable Catch in all regions except Normandy (Fig. 3). More recently, following demands by commercial sea-urchin divers, a stock assessment has been carried out by IFREMER in 2002 for the Southern Brittany area and a potential fishing biomass of 18 T has been estimated, and a small fishery may be opened in 2003 (Billy & Péronnet 2003).

A mass mortality in 1996 to 1997 have devastated the stocks in the Bay of Morbihan (Southern Brittany) and in central Northern Brittany (Zone of St Malo). No pathogenic agent have been identified with certainty in the wild, however, Nicolas et al. (2002) isolated and described a bacterial species, *Vibrio carchariae*, as the main pathogenic agent involved in mass mortalities that occurred

at the same time in land based operations. It is genetically and phenotypically close to *Vibrio fluvialis II* (Li et al. 1998) found in China on *H. discus hanai*. Recreational fishing was closed in 1998 and the opening of the commercial fishing season was delayed. Fishing started again in 1999, but catches have remained low in these zones. Divers report that outbreaks of the disease in these areas are still occurring each year late in the summer: severe mortality through all size classes was observed at the opening of the fishing season in September (Jehanno, pers. comm.). Although there is no scientific evidence to support this, the disease possibly becomes dormant during winter and is activated by high summer temperature. Figure 4 presents an interesting correlation between the areas of severe mortality observed by divers and local communities and sea surface temperature at the end of August. The disease is currently being studied more extensively.

Guernsey and Jersey (Channel Islands)

After 8 y of fishing with SCUBA, the commercial abalone fishery was closed in Guernsey in 1973 and has never been reopened since. Only shore gathering during spring tide, outside the reproductive season, is permitted nowadays (Mgaya & Mercer 1994). Commercial fishing using SCUBA, however, may be permitted again because the stocks seem to be recovering (Bossy, pers. comm.).

In Jersey, there is no commercial fishery. Only a recreational fishery is allowed and is conducted by fishing at low tide or "pêche a pied" as it is known locally. Ormer fishing is a very emotive subject in Jersey and is considered part of their heritage by the local community. Abalone aquaculture was attempted recently, but the summer mass mortalities wiped out the entire stock, and thus, there is no large scale aquaculture. After the disease outbreak in 1997, there was a total ban on ormer fishing until 2002. Recreational fishing regulations are complex and include a closed season between the May 1 and August 31, a minimum shell length of 8-cm, and the activity may only be carried out on the first day of each new moon or full moon and the three following days. Breathing apparatus, face visors, goggles, or masks are forbidden while fishing any shellfish other than crab. An abalone population survey carried out in 2002 provided evidence that the population was approaching pre-mortality levels and the ban on fishing is to be lifted (Morel, pers. comm.).

Spain

A commercial abalone fishery operated in Galicia from 1989 to 1993. In 1993, the fishery was closed following the discovery of PSP toxins by the Japanese in imported Spanish abalone. (Bravo et al. 1999, Bravo et al. 2001, Nagashima et al. 1995). There was no local demand to maintain the fishery. Following the study by Bravo et al. (2001) suggesting that toxins were contained only in the epithelium of the side of the foot, the fishery was reopened in April to May 2002. Almost all catches are exported, mostly to Asia. Abalone were sold in their shell at a minimum price of 24 €/kg in 2002. The demand has been variable possibly because of the small quantities offered on the market by the fishermen.

Fishing is carried out over the entire Galician coast, but most of the catches are in sheltered areas, which are more accessible (Juan Freire, pers. comm.). Catches are more important in the south, where large coastal embayments dominate the coast. The more exposed northern coast receives less attention. For example, in Cangas, where a large proportion of the fishery is carried out,

Figure 1. Fishing zones of the French ormer fishery since 1994. Each zone is managed by a local fishing committee.

TABLE 1.

Change in quota tonnage and numbers of divers (in brackets) over time in each fishing zone since the opening of the fishery in 1994.

Year of Activity	Nord-Finistère	Paimpol	S' Briec	S' Malo	Cherbourg	TAC (tons)
End 94	9.6 (16)	3 (12)	—	12 (12)	21 (6)	45.6
Early 95	9.6 (16)	4 (12)	—	18 (12)	21 (6)	52.6
95–96	10.8 (9)	6 (12)	—	36 (12)	21 (6)	73.8
97–2000	15 (10)	18 (11)	8 (8)	36 (12)	21 (6)	96
2001–02	10 (10)	18 (11)	8 (8)	36 (12)	21 (6)	91

abalone divers operate from May to September (4 mo). A minimum shell length of 8 cm and daily maximum catch quota of 5 kg/diver with a maximum of 15 kg/boat, are applied. In 2002, Cangas had seven boats with three divers each. Divers often combine abalone and sea urchin fishing. There is no regular stock assessment of the fishery and no information on the extent of poaching. Since late 2002 all coastal fisheries were stopped, following the major oil spill caused by the ship "Le Prestige" in Northern Spain.

North Africa

Although ormers are found on the north-west African coast, very little is known about the fishery. Exploitation of the resources by local fishermen has been encouraged by foreign traders, mostly from Asia. The extent of exploitation of wild populations and any management is not known.

Aquaculture

The first technical studies of ormer culture in France were carried out in the late 1970s and early 1980s by Flassch and Aveline (1984), Koike (1978), Koike et al. (1979), and Cochard (1980). They developed techniques for rearing, conditioning, and spawning (reviewed by Mgaya & Mercer, 1994). These studies concluded, however, that ormer culture was not economically viable, mainly because of the low market value of abalone at the time. Ormer culture has, therefore, not developed much in Europe. Ireland and the Channel Islands (2–3 tons/year) are the only established producing countries today. Ireland has introduced and

acclimatized both *H. tuberculata* and *H. discus hannai*. Few studies have been carried out so far to compare the performance of the two species. Cultivation attempts have also been carried out in Scotland (Kelly & Owen 2002).

In France, culture techniques have been perfected more recently by the SMEL. The duty of the SMEL is to provide technical support to any company willing to establish a farm in the Department of La Manche. They contributed to the first study of the bacterial epidemic because they lost a great part of their stock during the first outbreak (Nicolas et al. 2002). Their recent work also included preparation of broodstock for reproduction (inversion of photoperiod cycle for spawning during daytime and reduction of the conditioning cycle to 1–2 mo), techniques for live transport, settlement induction using GABA, stocking density, and ammonia management in recirculation systems (Richard, pers. comm., Basuyaux & Mathieu 1999). So far, only one commercial hatchery has been established in the department of La Manche in 2002, and it aims to produce small cocktail-size abalone to supply Parisian restaurants. One attempt at grow-out farming in sea cages was also started near Paimpol in Brittany in 2002, but the farm was stopped in its early development phase in 2003 for private reasons (Arlin, pers. comm.).

DISCUSSION

The ormer is a traditional delicacy in France and the channel Islands (Clavier 1992, Mgaya & Mercer 1994). Ormers were fished and consumed some thousands of years ago and are even found in archeological sites around Brittany (Chauvaud, pers. comm.). In spite of this local market and recreational fishing pressure, ormer populations have persisted until now. The European abalone industry has, however, faced major problems in the last decade from the *V. carchariae* disease outbreak, oil spills, and paralytic shellfish poisoning. In addition to these problems, the high commercial value of abalone is constantly increasing pressure

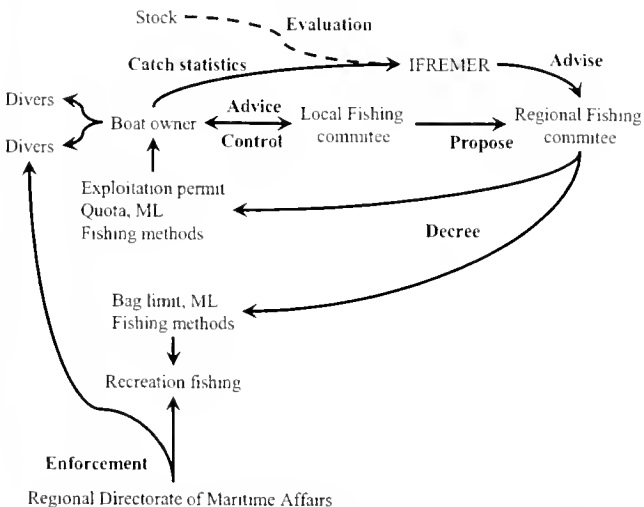

Figure 2. Administrative management of commercial and recreational ormer fisheries in France.

Figure 3. Quotas and official catches (FAO, 2000) over time in France.

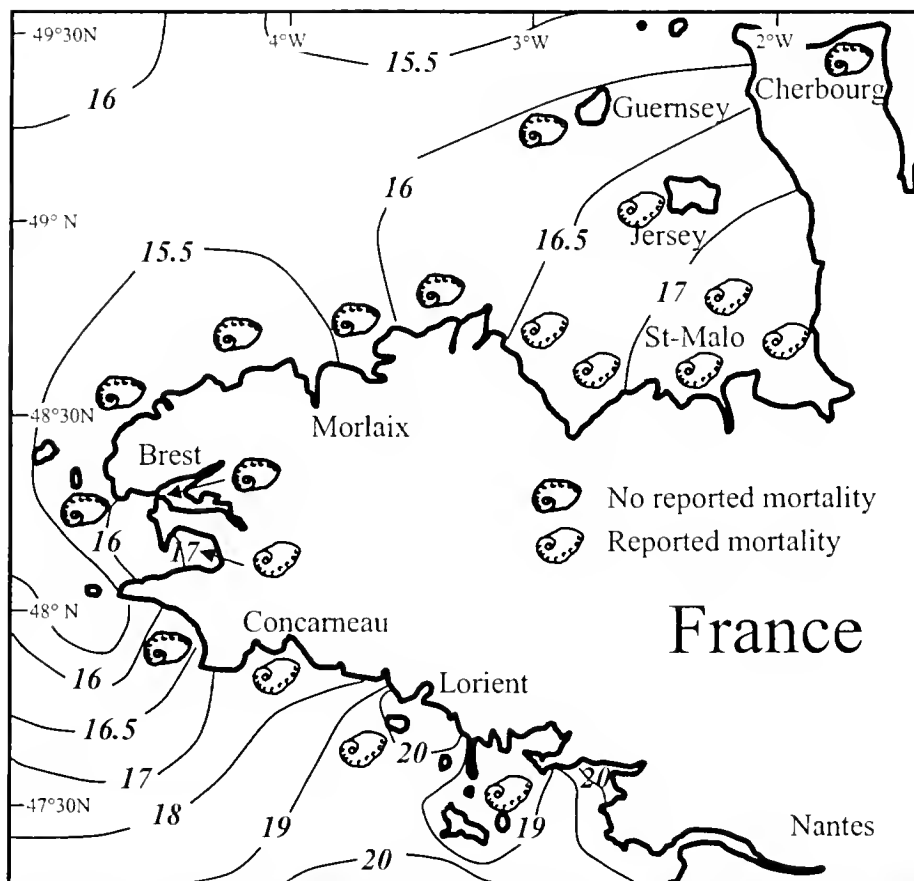

Figure 4. Map of Brittany showing the areas where mass mortalities have been witnessed (Mazurié & Richard 1999, Mazurié et al. 1999, and other testimonies collected by the authors) and the isotherm for the summer maximums (Compiled from: SAF O&SI (Satellite Application Facility) of EUMETSAT/Météo France in Lannion; Vincent & Kirc 1963, Lumby 1935).

on resources. Although difficult to assess, poaching is likely to considerably affect wild stocks because they are located in populated areas of Europe. Commercial divers often report that rocks have been turned over by poachers leaving devastated reefs behind them (Billy & Péronnet 2003). Possibly however, the cryptic behavior of ormers (Mgaya & Mercer 1994, Clavier & Richard 1984) may prevent the species from being fished out from the grounds where poaching is high, because larger rocks and deep crevices cannot be harvested.

In France abalone is considered as a minor fishing resource mainly because of its small TAC, low economic significance, and because it can sustain only a small population of fishermen. Management of the fishery is not, therefore, a priority and may seem inadequate. Although quotas were initially decided conservatively, allowing to small and very localized initial stock assessment, there are no fishery-dependent or independent stock assessments regularly carried out. Fishing pressure is, thus, not adjusted according to the biomass present. For example, in the area most affected by the mass mortality in 1996 to 1997, quotas were never reduced and the ban on fishing lasted for only 6 mo.

It is well known that overfished abalone stocks are slow to recover when fishing is stopped, and may collapse if fishing continues (Davis et al. 1996). The ormer stocks of Guernsey took at least 30 y to recover from a few years of intensive fishing. Sustainable management of an abalone fishery requires much attention

and must be tailored to protect the most vulnerable reefs (Shepherd 2000). Although management carried out by local fishing committees in France, they sometimes fail to decide on the closure of threatened fishery grounds (e.g., in the St Malo district where annual catch have become very low after the mass mortalities of 1996 to 1997). Local fishing committees often lack knowledge and expertise about the biology, ecology, and dynamics of abalone populations to take informed and preventive management decisions. Little information is collected about the wild populations, mainly because of a lack of financial support. The quota distribution often means that each fisherman receives too little quota to ensure a living and have to fish crustaceans or echinoderms to complement revenues. Higher revenue from a single activity could possibly increase the concern of fishermen to protect the stocks. In the department of La Manche, where there are less divers and more quota per person, the stocks appear to sustain a healthy industry (Richard, pers. comm.).

Commercial and recreational fishermen and seafood traders usually support the argument that poaching remains common in France, probably because of a lack of significant enforcement of the regulations by local authorities. It is common that occasional fishermen are not informed of the fishing regulations. Enforcement and broader public communication about the regulations and the biology and vulnerability of abalone populations, could be the first steps to prevent decline. Enforcement should be carried out within

an international framework to prevent the development of an organized poaching network (Campbell 2000, Daniels & Floren 1998). Fines and jail sentences should be similar to those imposed overseas (Masland & Barbee 2003).

The sustainability of European ormer fisheries cannot be assessed reliably, because there are too many unknown parameters remaining. The situation is alarming, however, considering the reasons for the collapse of many other abalone fisheries worldwide (Tegner 2000, Hobday et al. 2001, Shepherd et al. 1998, Campbell 2000, Shepherd & Rodda 2001), little has been done to protect European abalone populations. More research is required to understand stock dynamics, the effects of *V. carchariae* on the populations, and the risk of collapse of the population under the current management regimen. European research collaboration might en-

hance the development of the ormer industry and help to prevent the collapse of its stocks.

ACKNOWLEDGMENT

The authors acknowledge the help of Gerard Veron (IFREMER Brest), Olivier Richard & Olivier Basuyaux (SMEL, Blainville), Juan Freire (Universidade de Coruña, Spain), Simon Bossy (Fisheries officer, Guernsey), Greg Morel (Fisheries officer, Jersey), Stephanie Billy (Tethys environment, Lorient), André Arin (oyster farmer, Paimpol), Jehanno (fisherman, St Malo), Laurent Chauvaud (CNRS, Brest), and many others for providing the information used to compile this article. Special thanks to Dr. Rob Day (University of Melbourne, Australia) for his useful suggestions to improve the manuscript.

GROWTH AND SURVIVAL OF POST-LARVAL ABALONE *HALIOTIS DIVERSICOLOR SUPERTEXTA* (LISCHKE) USING AN ALTERNATIVE CULTURE METHOD IN THE LIGHT AND DARK

ADRIAN E. STOTT,¹ TOSHIO TAKEUCHI^{1*} AND YASUYUKI KOIKE²

¹Laboratory of Fish Culture, Department of Aquatic Biosciences, Tokyo University of Fisheries, 4-5-7 Konan, Minato, Tokyo 108-8477, Japan; ²Banda Marine Laboratory, Tokyo University of Fisheries, Banda, Tateyama, Chiba 227-0036, Japan

ABSTRACT—Stott's Abalone Postlarvae Production System (SAPPS) was developed as an alternative method for settling larvae and raising postlarval abalone. It allows continuous hatchery production of abalone without using live food. The new system was tested in a 28-day trial, both in the dark and light, on *Haliotis diversicolor supertexta*. Plates were sprayed with a mixture containing commercial, artificial micro particle diet 1 or 2, and a 1% agar solution and assigned a 10-L flow-through tank, either in the dark or light. The four treatments—Diet 1-dark (D1-D), Diet 1-light (D1-L), Diet 2-dark (D2-D), and Diet 2-light (D2-L) were replicated 3 times. The chemical composition of the two diets was similar although lipids were 21.05% in diet 1 compared with 13.74% in diet 2. Final survival was not significantly different ($P > 0.05$) among the treatments and ranged from 14.8% to 31.4%. The variable results for larval settlement and low postlarval survival in the first week was most likely due to unsatisfactory preconditioning of plastic plates with juvenile abalone trail mucus or weak settlement induction of this mucus. Although the light/dark factor was not significantly different ($P > 0.05$), abalone postlarvae fed diet type 2 (D2-D and D2-L) were significantly larger ($P < 0.05$) than those fed diet type 1 (D1-D and D1-L). The average growth rate per day was $43 \pm 4 \mu\text{m}$, $44 \pm 5 \mu\text{m}$, $51 \pm 4 \mu\text{m}$, and $53 \pm 4 \mu\text{m}$ for D1-D, D1-L, D2-D, and D2-L respectively. Diet 2 may have been more nutritionally complete than diet 1. SAPPS was used successfully in this trial to culture *H. diversicolor supertexta* postlarvae, regardless of light and natural food.

KEY WORDS: SAPPS, larval settlement, post-larval nutrition, micro particle diet, abalone, *Haliotis*

INTRODUCTION

Several problems have been identified and documented in regards to the current method of raising abalone on diatom biofilms. Abalone hatcheries often suffer 90% to 100% mortality by 2 mo postsettlement (Searcy-Bernal et al. 1992). Management of these diatom biofilms is often challenging and Hahn (1989) and Seki (1997) suggest that control of the initial food supply is still one of the most critical problems in hatchery seed production. It is a difficult task to maintain a supply of readily ingestible and digestible food (diatoms) for growing postlarvae (Kawamura et al. 1998). Alternative methods to those utilizing living diatoms, for abalone postlarval production, maybe beneficial to industry.

A mass culture system for the green alga *Ulva lens* on plastic plates has been developed to provide a settlement cue for larval abalone and provide a source of nutrition for the postlarvae. However, growth rates of postlarvae fed *U. lens* are significantly lower than favorable diatom species (Kawamura 1996, Seki 1997, Daume et al. 2000). Alternatively, Buchal et al. (1998) reported that postlarval *Haliotis rufescens* could be raised on dulce (*Palmaria mollis*) but direct utilization of dulce as a principle food source was only observed in abalone >3 mm in length.

Olin and McBride (2000) suggested that artificial diets are sometimes used by commercial abalone hatcheries to feed postlarval abalone once they have reached 2 mm in shell length. Stott et al. (2002) reported that young postlarval *Haliotis discus discus* grew well on a micro particle diet that was bound within an alginate gel which had been thinly pasted onto plastic plates. In a follow-up study, Stott et al. (2003a) developed a method for settling larval *H. diversicolor supertexta* directly onto plastic plates coated with the micro particle diet/alginate gel. Growth and survival rate of abalone postlarvae using this method was comparable

to that of post larvae grown using the diatom biofilm method. However, the alginate gel method would not be suitable for large-scale production of postlarval abalone (Stott et al. 2002, Stott et al. 2003b).

Consequently we focused our research on addressing this limitation and SAPPS was developed. This new method utilizes the temperature dependant setting properties of agar to cover plates, via spraying, with a micro particle diet/agar gel mixture. Commercial scale trials were previously conducted to test growth and survival rate of postlarval *H. diversicolor supertexta* using SAPPS compared with that using conditioned diatom biofilm (Stott et al. unpublished data). After 42 days abalone grown using SAPPS had reach an average size of 3.2 mm with a survival rate of 51.7% compared with a size of 2.2 mm with a survival rate of 10.6% for conditioned diatom biofilm.

The current trial was conducted to determine whether SAPPS could be used to culture *H. diversicolor supertexta* in small tanks. Two commercial, artificial micro particle diets were used and each was tested in the dark and light to determine if natural microalgal related food was affecting results.

MATERIALS AND METHODS

Methodology for SAPPS

Two experimental versions of the commercially available artificial microparticle diet "Plate Powder" were supplied by Adam and Amos Pty Ltd (Mt Barker, Australia). The diets were sieved and only particles of 53- μm or less were used in the trial. The original particle size of diet 1 was quite large and less than 10% of the diet passed through the sieve. However, the original particle size of diet 2 was smaller than diet 1, with over 70% of the particles passing through the sieve. Examination of both diets under a compound microscope at $\times 400$ magnification revealed that

*Corresponding author. Email: 9estott@hotmail.com

many of the ingredients were not finely ground during the initial grinding process when the diets were produced. Large clumping of individual ingredients was observed among particles that failed to pass through the sieve.

A solution of agar was prepared by dissolving 10 mg/mL of agar powder (Kokusan Chemicals; Tokyo, Japan) in boiling, deionized water. Once the temperature of the solution had fallen to 60 °C, 100 mg/mL of micro particle diet was added to the solution and the contents were thoroughly mixed. Results from pretrials confirmed that agar by itself (without microparticulate diet) was inappropriate for supporting high growth and survival of postlarval *H. discus discus*.

The resulting solution was then transferred to a MK-7 fine mist sprayer (Calmar; NY, USA) and the temperature was maintained at approximately 50 °C. Each plastic plate (dimensions of 22.5 cm × 11.5 cm) was sprayed (individually) after being removed from the experimental tank and allowed to drain for approximately 10 sec. Plastic plates were sprayed by holding them 30 cm away from the sprayer. The entire surface of the plate was subsequently sprayed with solution contained in the MK-7 fine mist sprayer. Pretrials confirmed that the SAPPs methodology did not compromise postlarval survival. Results from pretrials also confirmed that newly metamorphosed postlarvae did not incur mortality via drowning from the fine mist produced by the sprayer and the temperature of the agar/diet solution dropped to safe levels during the process of spraying (as the solution moves through the air and contacts with the wet plastic plates). Each side of the plastic plate was sprayed twice (approximately 0.4 mL of solution per side). Once the spray process was complete, the plate was quickly placed back into the experimental tank.

Spawning and Larval Settlement

Broodstock *H. diversicolor supertexta*, at a ratio of two females to one male, were induced to spawn at Banda Marine Laboratory, Tokyo University of Fisheries, using UV light and temperature shock. After hatching, larvae were reared at three larvae/mL in a 100-L flow-through system with a flow rate of 400 mL/min and a temperature of 23 °C. Larvae were deemed competent for settlement when the third tubule on the cephalic tentacle appeared. At this stage larvae were concentrated, counted, and then transferred to the laboratory ready for assignment to the experimental tanks.

Seven days before placing the plastic plates in the experimental tanks, they were preconditioned with juvenile abalone mucus to act as an attachment and settlement inducer. This was achieved by spraying the appropriate diet onto the plastic plates using the method stated earlier. The plates were then placed vertically into a tank with a small number of juvenile *H. discus discus* (20–50 mm) and the tank covered with black plastic to prevent the growth of microalgae. The juvenile abalone were encouraged to graze the diet coated plates and the food was reapplied via the spray system every second day for a period of 5 days.

Two conditioned plates (with the appropriate diet) were hung vertically in each 10-L experimental tank and approximately 2,000 larvae were introduced. Larvae were allowed to settle for 24 h, and then the plastic plates were removed and the number of attached larvae was enumerated for each tank. In this study, abalone larvae were considered to have completed metamorphosis when they had dropped their velum and showed evidence of peristomal shell growth.

Unattached larvae in the experimental tanks were discarded

along with the seawater when the tanks were cleaned. All tank surfaces were scrubbed with a scrubbing brush and washed with freshwater to remove any larvae that had attached. The tanks were then refilled with fresh seawater, ready for the postlarval grow-out phase of the trial.

Post-larval Grow-out

The trial consisted of 4 treatments: Diet 1-dark (D1-D), Diet 1-light (D1-L), Diet 2-dark (D2-D), and Diet 2-light (D2-L), each replicated three times (total of 12 experimental units). Independent tanks were used for replicates. Each experimental unit was assigned a 10-L flow-through tank that was supplied with charcoal filtered water at 250 mL/min. The tank's outer surfaces were painted with black paint and 150 µm was glued over the outlet of the tank to stop dead larvae from being flushed out of the tanks. The tanks to be placed in the dark, D1-D and D2-D, were covered with black plastic. The tanks remaining in the light, D1-L and D2-L, were left uncovered and exposed to a natural lighting regimen (approximately 7,000 LUX during daylight hours).

Food was sprayed onto the plastic plates using the earlier mentioned method, on day 1 (after the 24 h settlement period) and every second day thereafter. Tanks were siphoned every second day and the siphoned water samples were examined and the number of dead postlarvae tallied to calculate percentage survival. Postlarvae from the siphoned water samples were transferred to a glass slide with a pipette and examined to confirm if they were dead. This process was also used to determine the relative proportion of mortality of larvae (no peristomal shell formation) and postlarvae (peristomal shell formation). Tanks were also thoroughly scrubbed twice per week to remove any attached microalgae, etc. At the end of the experiment the total number of postlarvae remaining in each tank was enumerated. This number was compared with previously recorded survival data to validate the accuracy of the methodology.

Post-larvae were sampled twice per week by randomly removing 10 animals from plastic plates in each tank using a soft brush. The size (maximum standard length) of postlarvae was taken using a compound microscope fitted with an ocular eyepiece. Water temperature was measured using a standard thermometer and averaged 25.3 °C ± 0.9 °C.

Approximate Analysis and Particle Size Determination of the Diets

Proximate analysis of the diets for moisture, crude protein, crude lipid, and crude ash was performed using the methodology outlined in Hernandez et al. (1995).

The particle size of the artificial diets was determined by randomly extracting 40 particles and measuring the size under a compound microscope fitted with an ocular eyepiece, at ×100 magnification.

Statistical Analysis

Statistical analysis was conducted using the computer package SYSAT (SPSS Inc., IL USA). Before conducting statistical ANOVAs, normality was confirmed using normal probability plots and homogeneity of variance was validated utilizing Levene's test. Data was transformed where necessary and a one-way ANOVA performed. Differences in means were determined using Tukey's test.

RESULTS

The mean composition of the diet 1 and diet 2 were similar, with exception to crude lipids (Table 1). Crude lipid was 21.0% for Diet 1 compared with 13.8% for Diet 2. The particle size of diet 1 was slightly larger than diet 2; $34 \pm 11 \mu\text{m}$ compared with $31 \pm 6 \mu\text{m}$.

Attachment of larvae in the different treatments was variable and patchy on the plates in the experimental tanks. Final mean settlement of larvae was 241 ± 142 , 173 ± 87 , 333 ± 56 and 195 ± 60 in D1-D, D1-L, D2-D, and D2-L respectively (Table 2).

Mortality of postlarvae in the different treatments was high in the first week, ranging from 55.4% to 74.8% (Fig. 1). The majority of these mortalities were observed to have no peristomal shell growth. Thus, a high percentage of the mortalities in the first week were larvae that had attached but failed to complete metamorphosis. Very little mortality occurred after the first week and final mean mortality of postlarvae in the different treatments ranged between 14.8% and 31.4%.

The daily growth rate of postlarvae in all treatments increased in the ensuing weeks (Fig. 2). The final mean size of post larvae was significantly higher ($P < 0.05$) in D2-D ($1,695 \pm 148 \mu\text{m}$) and D2-L ($1,752 \pm 134 \mu\text{m}$) compared with that of D1-D ($1,488 \pm 153 \mu\text{m}$) and D1-L ($1,512 \pm 181 \mu\text{m}$).

DISCUSSION

H. diversicolor supertexta postlarvae grew well using SAPPS, regardless of light, suggesting that they can grow without the requirement of light or photosynthetic live food. Plastic plates in D1-D and D2-D were kept in the dark to have been relatively free of microalgae. Additional measures to limit microalgal growth in the experimental tanks were also included (e.g., supplying tanks with charcoal filtered water and scrubbing them twice weekly). Thus, postlarvae were able to gain adequate nutrition via SAPPS and those fed diet 2 grew at over $50 \mu\text{m/day}$.

Post-larvae that were grown in the dark may have gained exogenous nutrition from the artificial diet, bacteria that proliferated on the plates and mucus deposited by the juvenile abalone. Takami et al. (2000) found that *H. discus hannai* shift from yolk energy source to particulate food by the time they reach $500 \mu\text{m}$. Takami et al. (1997) reported that all *H. discus hannai* larvae that were raised on an unsuitable diatom biofilm died before they reach $500 \mu\text{m}$ and all those raised exclusively on abalone mucus died before they attained a size of just over $700 \mu\text{m}$. Postlarvae over 1 mm in length require high levels of digestion of diatoms in addition to any extracellular substances for favorable growth (Kawamura 1996). Thus, in this study, postlarval abalone fed diet 2 grew to about

$1,700 \mu\text{m}$ and the growth rate doubled from week 1 to week 4 (approx. $30 \mu\text{m}$ to $60 \mu\text{m}$). Therefore, postlarvae were most likely gaining a high level of nutrition from the artificial micro diet. Visual observations also confirmed that food was in the gut and mortality after week 1 was minimal. However, the influence of bacteria on growth and survival of postlarval abalone was not determined.

Post-larval abalone cultured in the dark grew as well as those grown in the light. Photosynthetic food that may have grown on the plates, provided postlarvae no advantages in terms of growth and survival. It seems that abalone in this trial had no requirement for light. However, it is also necessary to investigate the opposite scenario because complete, continuous darkness could potentially offer postlarval abalone advantages in terms of growth and survival. Adult and juvenile *Haliotis spp.* mainly feed at night (Ino 1943, Sakai 1962, Uki 1981) and grow better when cultured in the dark (Ebert & Houk 1984). However Velez-Espino (1999) found that there was no evidence of nocturnal feeding habits in postlarvae. Abalone postlarvae remained attached to the plastic plates but become increasingly sensitive to light after they develop their first respiratory pore (Hahn 1989). Thus, postlarval feeding most likely takes place regardless of light or time of day. Darkness at this trial provided no advantages in terms of growth and survival.

The final mean size of postlarvae fed diet 2 was greater than that of postlarvae fed Diet 1. Proximate composition of the diets was similar, apart from a higher percentage of crude lipids in Diet 1, compared with Diet 2. Uki et al. (1985) found that growth performance of *H. discus hannai* was maximized at 5% crude lipid inclusion in an artificial diet. Other species such as *H. tuberculata* have an optimum growth rate at levels as low as 3.11% crude lipid (Mai et al. 1995). In the current trial, the artificial diet was supplied by a commercial manufacturer and no information was made available regarding the ingredients or binders incorporated into the diet. The only obvious difference after proximate analysis was lipid content. Total crude lipid in diet 1 was 21% compared with only 13.8% in diet 2 and this high inclusion of lipid, although not conclusive, may have negatively affected postlarval growth. Processing the artificial micro particle diet for application via SAPPS may have affected the original gross composition or nutritional balance. The sieving process resulted in selection of small particles ($< 53 \mu\text{m}$), whereas larger particles were excluded. The original particle size of diet 1 (before sieving) was much larger than diet 2 and this resulted in high particle retention when sieving with a $53\text{-}\mu\text{m}$ sieve. This may have caused higher selection of particles that contained high levels of lipids. However, because the crude lipid content of the diets before sieving was not determined and a list of ingredients and methods used to make the diet were not available, the exact reason for such a high level of lipids in the diet remains unclear.

In future, it is recommended that ingredients incorporated into diets that are applied using SAPPS, be thoroughly ground. Additionally, after processing the final diet, if the particle size of the diet is over $53 \mu\text{m}$, the diet should be ground down further to create a finer particle size before sieving. Artificial abalone diets that have been made for juvenile or adult abalone can also be used in SAPPS provided they are ground down to a fine powder.

Extremely high postlarval mortality in the first week of the trial in all treatments was due to a high rate of unsuccessful metamorphosis of larvae. Many of the larvae attached to the plates, dropped their vellum but failed to deposit peristomal shell. These larvae died before the end of the first week. However, larvae that com-

pleted metamorphosis were in high densities in small patches on the plates. Thus, it is possible that the plates were not adequately conditioned with mucus due to the fact that the number of juvenile abalone that were placed into the tanks to condition the plates with mucus for larval settlement, were too low. It was also observed that food sprayed on the plates for juvenile abalone during the conditioning period was not heavily grazed. Mucus was only deposited on the regions of the plastic plates where juvenile abalone grazed. Other regions of the plastic plates (with no mucus) larvae attached at lower densities and most of these larvae failed to complete metamorphosis. In a previous trial, *H. discus discus* larvae attached to blank plastic plates at a rate of up to 20%, but successful metamorphosis occurs in less than 5% of the larvae (Stott et al. In press). In the same study, attachment and metamorphosis was increased to about 80% by spraying freeze-dried algal powders (*Spirulina platensis* or *Chlorella vulgaris*) onto plastic plates and then conditioning them with abalone mucus by allowing juvenile *H. discus discus* to graze the plates. Takami et al. (1997) reported that *H. discus hannai* settled on abalone mucus conditioned plastic slides at a rate of 48.7% and that all postlarvae died by the end of the third week. This documents a much higher rate of attachment than the current trial but no larvae completed metamorphosis (and only 10% attached) in a control group that was offered no settlement stimulus. Additionally, as with our previous trial, the same species of juveniles as the larvae were used to condition plates in the mucus treatment.

It is possible that mucus from juvenile *H. discus discus* was not

Figure 1. Survival rate (\pm SD) of postlarval *Haliotis diversicolor supertexta* fed two different artificial micro particle diets in the dark and light over a 4-wk period.

a strong attachment and metamorphosis inducer for larval *H. diversicolor supertexta*. Seki and Kanno (1981) found that larval *H. discus hannai* settled on mucus from 4 different *Haliotiodes* but not on mucus from a number of mollusc from different genus to *Haliotis*. However, in that study, percentage settlement was not determined and *H. diversicolor supertexta* was not tested. *H. diversicolor supertexta* is a small species of abalone that spawns sporadically over the summer period whereas *H. discus discus* is a relatively large species of abalone that spawns usually once in autumn (Hahn 1989). Attachment and metamorphosis rates of larval abalone may be improved by using juvenile abalone from the same species for conditioning plates.

After the first week, postlarval survival was very high. Even though the average water temperature was over 25°C, the use of artificial diets did not seem to adversely affect culture conditions. Hahn (1989) suggests that most abalone farmers stop using artificial diets when water temperatures rise above 24°C. The methodology for SAPPs results in the artificial micro particle diet being coated with agar. Stott et al. (2003b) found that nitrogen leaching from an artificial micro diet after 12 h immersion was nearly reduced by half when binding the diet in an alginate gel compared with adding the diet directly to the water column. Although this was not quantified in this trial, it is likely that binding the diet in an algal gel would protect it from bacterial degradation and leaching that may potentially adversely affect water quality.

There is a need for greater research in this area before modi-

Figure 2. Mean growth rate ($\mu\text{m}/\text{day}$ (\pm SD) for postlarval *Haliotis diversicolor supertexta* fed two different artificial micro particle diets in the dark and light over a four week period.

fying SAPPS for use in industry. It will be necessary to determine optimum concentration of agar as well as feeding frequency. A major disadvantage of SAPPS is that it is an extremely intensive method and spraying the plates requires much effort that may translate into high labor costs. It would be beneficial to spray plates as infrequently as possible without adversely affecting post-larval growth and survival. SAPPSS allows application of artificial diet to wet plates but some of the diet is lost when replacing plates into the tanks.

In the near future, commercial trials of SAPPSS will be con-

ducted using state of the art spraying technology and incorporating new larval settlement technology.

ACKNOWLEDGMENTS

The authors thank the staff from Banda Marine Laboratory for their assistance throughout the trial. Many thanks to Joel at Adam and Amos Pty. Ltd. (Mt Barker, Australia) for supplying the artificial diets ("Plate Powder") used in this trial. Finally, thanks to Ronald Mitchell and anonymous colleagues for reviewing the manuscript.

EFFECT OF TEMPERATURE ON THE EARLY DEVELOPMENT OF *HALIOTIS DIVERSICOLOR* REEVE

JUNYI LU,* QIANG LIN, YANYAN SUN, JUNQING SHENG AND QINGXIANG CHEN

Institute of Aquatic Economic Animals and Guangdong Provincial Key Laboratory for Aquatic Economic Animals, Zhongshan University, Guangzhou 510275, China

ABSTRACT The effect of temperature on the early development of *Haliotis diversicolor* Reeve was studied as a strategy to define the optimum temperature range for experiments on early developmental conditions of this species. The survival rate of *Haliotis diversicolor* Reeve of different stages of early development varied significantly at different temperatures (17°C, 21°C, 24°C, 27°C, 31°C, and 33.5°C) ($P < 0.01$). In the cleavage period, the survival rate was 1.7% at 17°C and 99.4% at 27°C. When the water temperature was 33.5°C the survival rate was 17.9%, much lower than 97.9% at 31°C. The other 3 embryonic periods, including embryonic development, postembryonic development, and emergence stage of the 1st breathing pore, also showed the similar trends with variations in temperature. When temperature increased between 18°C and 30°C, the early developmental rate accelerated, the developmental time shortened and survival increased. The relationship between the developmental rate or the developmental time and water temperature can be expressed by the following formula: $Y = 0.0541 / (1 + 5.8381e^{-0.2532t})$ ($r = 1-0.7014$, $P < 0.05$). The first trochophore needed 20 h to hatch out with an instantaneous hatching rate of 0.2% at 17°C and the total hatching rate reached 2.5% at 28 h. When temperature was maintained at 27°C the time of first trochophore hatching was at 8 h postfertilization (h.p.f.) with an instantaneous hatching rate of 10.3% and the highest total hatching rate was 96.4% at 22 h.p.f. when the incubation ended. The total hatching rate declined to 85.3% at 33.5°C. The settlement of trochophore was also affected by temperature. The trochophores started to settle at 65 h.p.f. with a low settlement rate of 0.5% only at 17°C and started to settle at 55 h.p.f. with the highest settlement rate of 53.2% at 27°C and only 1.2% at 33.5°C. The results showed that the optimum water temperature for artificial reproduction and seed breeding of *H. diversicolor* was 24°C to 28°C.

KEY WORDS: *Haliotis diversicolor* Reeve, early development, temperature

INTRODUCTION

Haliotis diversicolor Reeve is a species of abalone especially popular in South China because of its appropriate size and unique flavor. The reproduction and breeding of abalone is the foundation of commercial culture. The reproductive cycles of several important abalone species have been studied. The reproductive biology of the Donkey's ear abalone, *H. asinina* Linné were studied, including the sex ratio, initial size at sexual maturity, spawning period, fecundity, and so on (Capipin et al. 1998). Jarayabhand et al. (1995) reported on the embryonic and larval development of *H. ovina*. Early development showed differences in developmental stages between *H. asinina* and *H. ovina* in Thailand, physicochemical factors having important effects on the growth and survival. (Jarayabhand & Paphavasit 1996). It has been reported that salinity plays an important role in the early development of oysters (Tan & Wong 1996) and the juvenile abalone (Chen & Chen 2000). The hatching, larval growth, survival, and settling of oysters were reported to be affected by salinity (Liu et al. 1992, Madrones-Ladja et al. 2002a, Nell & Holliday 1988, Tan & Wong 1996). Salinity, micro algal diet, and rearing conditions also affected gonad maturity and fecundity, early development, and larval growth of the window-pane shell (Madrones-Ladja et al. 2002a, Madrones-Ladja et al. 2002b). Dos Santos & Nascimento (1985) reported that the normal early development of the mangrove oyster was influenced by gamete density, salinity, and temperature. The early development of *H. diversicolor* was suggested to be divided into 4 periods, which were cleavage, embryonic development, postembryonic development, and emergence stage of the 1st breathing pore (Lu et al. 2001). This study investigates the effect of temperature on the early development, developmental rate, hatching, and settlement of the trochophore.

MATERIALS AND METHODS

Materials and Water Treatment

The fertilized eggs used in the incubation experiment were collected by the following procedure: 2⁺-year-old parental abalone (shell length of 50–65 mm and body weight of 41.5–62.5 g) were induced to spawn by temperature stimulation and then the eggs were artificially fertilized (Lu et al. 2001).

To test the variance in the embryonic development of *H. diversicolor* at different water temperatures, we adopted 6 different temperature ranges: 17°C, 21°C, 24°C, 27°C, 31°C, and 33.5°C ($\pm 0.5^\circ\text{C}$). The seawater used in the experiments was treated by double sand-filtration (particle diameter, 0.05–0.10 mm) and bio-filtered at salinities of 28‰ to 35‰ and at pH of 8.2–8.5.

Experiments

All experiments were conducted in triplicate at six different water temperatures.

Embryonic Development

The fertilized eggs were incubated in 500 mL glass beakers under different water temperatures. After fertilization, 2-mL samples, which were at a density about 10 eggs/mL, were taken every 3–5 min for microscopic examination to observe the cleavage progress. One hour later, samples were taken every 10 min for observation of embryonic development, and larvae were counted every 0.5 h.

Trochophore Settlement and Survival

One thousand trochophores were stocked in 150-mL glass beakers at a density of 10 individuals/mL at different temperatures. Samples were examined to observe the shaping of larval organs

using a binocular dissecting microscope, every 2 h, until all of them metamorphosed to settle or die.

Statistical Analysis

One-way ANOVA was used to examine the effects of temperature on survival of different stages in the early development, and regression analysis was used to test the relationship between developmental rate and temperature. When necessary, data were treated and assessed statistically by using 11.5 SPSS (Statistical Program for Social Sciences) computer software.

RESULTS

Effect of Temperature on the Early Development of *H. Diversicolor*

The survival rate of different stages in the early development varied greatly at temperatures of 17 C, 21 C, 24 C, 27 C, 31 C, and 33.5 C ($P < 0.01$). In the cleavage period the survival rate was 1.7%, 65.1%, 88.5%, 99.4%, and 97.9% at the temperature of 17 C, 21 C, 24 C, 27 C, and 31 C, respectively. The results indicated that 27 C was the optimum temperature for the early development because of its highest survival rate of 99.4%, and the next highest was 97.9% at 31 C. However, when the water temperature increased 33 C to 34 C the survival rate decreased to 17.9%. In addition, the survival rate of other periods such as embryonic development, postembryonic development, and emer-

gence stage of the 1st breathing pore (see Lu et al. 2001) also showed similar trends at water temperature of 17 C to 34 C, and temperatures between 24 C and 27 C also had higher survival than the others (Table 1). The survival rate at the same temperature among different stages didn't show significant variance ($P > 0.05$).

Effect of Instantaneous Water Temperature on the Early Developmental Rate

The early developmental time and its rate were influenced by instantaneous water temperature. The early developmental time shorted when the water temperature increased from 16 C to 32 C. When the temperature increased to 34 C, the developmental rate slowed down and a longer time was needed to develop. The developmental time was directly related to water temperature when temperatures ranged from 16 C to 30 C. In contrast, the developmental rate was inversely related to water temperature between 16 C and 30 C (Fig. 1). The relationship between the developmental rate or the developmental time and temperature can be expressed by the logistic formula:

$$Y = 0.0541 / (1 + 5.8381e^{-0.2532 t}) \quad (r = -0.7014, P < 0.05).$$

Y: developmental rate or the developmental time t: temperature

Effect of Temperature on the Hatches of Trochophores

Under the artificial breeding conditions, the incubation of the fertilized eggs of *H. diversicolor* was mainly affected by temperature. The first trochophore required 20 h to hatch out with an instantaneous hatching rate of 0.2%, and the total hatching rate reached 2.5% at 28 h postfertilization (h.p.f.), and the final survival rate was 16.0% at a mean temperature of 17 C. The trochophores started to hatch out at 10 h. p. f. at 21 C and 8 h.p.f. at 24 C. When the temperature was maintained at 27 C, the time was 8 h with an instantaneous hatching rate of 10.3% for the hatching out of the first trochophore, and this produced the highest total hatching rate of 96.4% and a survival rate of 81.85% at 22 h. p.f. The total hatch rate declined to 94.9% at 31 C and 85.3% at 33.5 C

The time of the first trochophore of hatching out and instantaneous hatching rate.

Temperature (C)	17	21	24	27	31	33.5
Time (h)	20	10	8	8	6	8
Instantaneous hatching rate (%)	0.2	1.5	6.8	10.3	8.1	11.5

Figure 2. The hatching rate and survival rate of trochophores at six temperature levels.

with a survival rate of 76.08% and 72.33%, respectively (Table 2, Fig. 2 and Table 3).

Effect of Temperature on the Settlement of Trochophores

Temperature also affected the settlement of trochophores. The trochophores started to settle at 65 h, with a low settlement rate of 0.5%, when the mean temperature was 17°C. When the water was 21°C, the trochophores started to settle earlier at 55 h, and the number of settled individuals increased to 17.4%. The settlement rate was 53.2% at 27°C; 34.9% at 24°C; 29.1% at 31°C and 1.2% at 33°C to 34°C (Fig. 3). In addition, results showed that the instantaneous settling rates were 5.30%, 85%, 168%, 87%, and 5% at 17°C, 21°C, 24°C, 27°C, 31°C and 33.5°C, respectively (Table 4).

DISCUSSION

We found that salinity was relatively steady at 28‰ to 35‰ and pH was 8.2–8.5 whereas temperature varied from 12°C to 32°C in the artificial breeding of *H. diversicolor* (unpublished), and it had also been proven that temperature greatly influenced early development, seed breeding, and growth of *H. diversicolor* (Chen & Chen 1999). The survival rate of different stages in the early development showed significant difference within different temperature ranges ($P < 0.01$). Water temperature played an important role in the fertilization of eggs and resulted in the failure of fertilization at lower (16°C to 22°C) or higher (33°C to 34°C) temperatures, which was at a rate of 33.5% and 45.8%, respectively. According to the observation, low temperature (17°C) can also terminate the development of the cleavage stage of the fertilized eggs at a rate of 97%. From Table 1 and Figure 1 we can see that the final survival of juveniles was higher at 24°C to 31°C than that at 17°C and 33.5°C with shorter developmental time and faster developmental rate. Generally speaking, the shorter time of the incubation and hatching, the shorter time the individuals were exposed to adverse environmental factors such as parasitic fungi or predation by copepods.

Within the optimum range of temperature, the higher the tem-

Figure 3. Variation of the settlement of trochophores at six temperature levels.

perature, the shorter the developmental time, which was similar to that of fish such as eel *Anguilla japonica* (Xie et al. 1995), *Silurus glodatovi meridionalis* Chen (Chen et al. 1998), *S. asotus* Linnacus (Xiao et al. 1998) and *Megalobrama hoffmanni* (Ye et al. 1998), and snail *Babylonia formosae habei* (Zheng et al. 2000).

The first trochophore of *H. diversicolor* hatched out at 20 h.p.f. at 17°C, 10 h.p.f. at 21°C, 8 h.p.f. at 24°C and 27°C, 6 h.p.f. at 31°C, and 8 h.p.f. at 33.5°C (Table 2). Jarayabhand et al. (1995) reported that the trochophores of *H. ovina* hatched out at 7–8 h and trochophores of *H. asinina* hatched out at 5 h (Jarayabhand & Paphavasit 1996) at the average temperature of 29°C. The latter species was a little earlier than the former in hatching out.

Planktonic marine invertebrate larvae experience high mortality rates. Processes during these early vulnerable stages of development are an important determinant of the dynamics of marine invertebrate populations (Drent 2002). Those that hatched out at temperatures lower than 18°C or higher than 32°C had lower swim-up rates and settling rates. When the temperature exceeded 32°C the hatching rate was relatively high, but more trochophores were malformed and incapable of swimming or settling, and this prolonged the duration of settling and finally the animals died of fatigue. This was similar to results obtained on *H. discus hamai* Ito (Chen et al. 1977).

According to the results of the experiments, the optimum temperature for incubation and seed production was 24°C to 28°C and this proved feasible in large-scale artificial breeding of *H. diversicolor*. We got mass production of juveniles (shell length at 1.8–2.5 cm) at densities of 4,806 ind/m² in 2001 (Lu et al. 1999).

FATTY ACID COMPOSITION OF EGGS DERIVED FROM CONDITIONED AND WILD CAUGHT GREENLIP ABALONE BROODSTOCK (*HALIOTIS LAEVIGATA*)

SABINE DAUME^{1*} AND STEPHEN RYAN^{1,2}

¹Department of Fisheries, Research Division, PO Box 20, North Beach, WA 6920, Australia;

²Great Southern Marine Hatcheries, PO Box L34, Little Grove, Albany WA 6330, Australia

ABSTRACT In the present study, the fatty acid profiles of eggs spawned from conditioned and wild caught greenlip abalone broodstock (*Haliotis laevigata*) were compared. Lower proportions of polyunsaturated fatty acids (12% and 9%) compared with monounsaturated (44% and 45%) and saturated fatty acids (32% and 34%) were present in eggs of conditioned and wild caught broodstock respectively. Relative amounts of individual saturated and monounsaturated fatty acids were similar in eggs of both wild caught and conditioned broodstock. The relative proportions of some polyunsaturated fatty acids of the broodstock diets were reflected in the eggs and varied between batches of conditioned and wild broodstock. Formulated feed has high linoleic acid (18:2n-6) and the proportion of this fatty acid was 10 times higher in eggs spawned from animals fed formulated feed than in eggs of wild caught broodstock. Eggs derived from wild broodstock, which feed preferentially on red seaweeds, showed about twice as much arachidonic acid (20:4n-6) compared with eggs from conditioned broodstock, which were supplied with a formulated diet low in arachidonic acid. Arachidonic acid is a major precursor of prostaglandins, which play a vital role in molluscan reproduction. In this study, the levels of ARA were higher in eggs than in the respective diets of the broodstock, except of the *Gracilaria* diet, indicating that ARA was preferentially incorporated into the eggs of broodstock feeding on formulated feed and *Ulva australis*. Results from the present study demonstrate that 3 mo of feeding on an altered diet is sufficient to alter the fatty acid profile of the eggs. This study shows high variability in diameter, weight, and biochemical composition of eggs between batches and spawning seasons. We present initial evidence that smaller eggs had higher lipid content with a higher larval hatch rate than larger eggs. In addition, larval settlement was negatively correlated with egg moisture.

KEY WORDS: abalone eggs, arachidonic acid, fatty acids, *Haliotis laevigata*, lipid

INTRODUCTION

Abalone farming is a well-established industry in many countries worldwide but is still in early development in Australia. Successful conditioning of broodstock is a crucial step for selective breeding programs to develop this growing industry. Gonad maturation and larval settlement success of abalone are known to vary seasonally (Webber 1970, Slattery 1992). However, large variability in spawning events, hatchability, and larval and juvenile survival rates has been observed during the same season between batches and hatcheries in Australia.

Formulated diets designed to maximize growth rates are not necessarily adequate to maintain viable, high quality eggs and larvae from captive broodstock. There is growing evidence that specific dietary lipids play an important role in gonadogenesis of abalone (Uki & Watanabe 1992, Nelson et al. 2002). Recently, Nelson et al. (2002) showed that variations of the C₂₀ polyunsaturated fatty acid (PUFA) in the digestive gland and foot tissue of *Haliotis fulgens* over the year coincided with variation in their macroalgal diets. This study indicated that abalone tissues directly reflect their diets. Furthermore, the authors suggested that arachidonic acid (ARA) is an essential fatty acid for the abalone *H. fulgens*. They concluded that essential fatty acids are derived from the algal diet and are most likely important in cyclical gonad development.

Studies of changes in biochemical composition such as fatty acids in mollusc eggs are scarce. Soudant et al. (1996) established that PUFA composition of great scallop (*Pecten maximus*) gonad was related to the fatty acid composition of the diet. Gallager & Mann (1986) reported a significant correlation between the initial egg lipid content and survival of the bivalve *Crassostrea virginica* larvae. In addition, the growth of *Ostrea edulis* was affected by the

amount of lipid present in larval and spat tissue (Laing & Millican 1986). Changes in biochemical composition during larval development were reported for scallops (Whyte et al. 1990, Farias et al. 1998), oysters (Ferreiro et al. 1990) and abalone (Litaay et al. 2001). Lipids in abalone eggs are known to partially fuel the metamorphosis of the larvae (Jaecle & Manahan 1989). Variations in lipid content and fatty acid profile have been shown, by Nelson et al. (2002), to be related to seasonal temperature fluctuations and variations of the diet may ultimately affect the success of the progenies.

In this study we determine the fatty acid profiles of eggs spawned from conditioned broodstock (feeding on formulated feed) and wild caught broodstock of *Haliotis laevigata*. In addition, 3 conditioning diets are tested with one group of female broodstock continually being fed the commercially used broodstock conditioning diet until spawning, the second group fed the green alga *Ulva australis* and the third group fed a red seaweed diet (*Gracilaria flagelliformis*, *Champia parvula*) for the last 3 mo before spawning, to examine if a dietary change affects the fatty acid composition of the eggs. The aim is to determine how the lipid quality of the broodstock diet affects the fatty acid composition of *H. laevigata* eggs and to evaluate the biologic consequences such as larval hatch rate, larval survival, and settlement performance. This information contributes to the knowledge on abalone broodstock quality as well as larval nutrition.

METHODS

Broodstock Collection and Maintenance

All broodstock was collected from the Southern Ocean in Western Australia, from waters between Augusta (115°16'E; 34°32'S) and Hopetown (120°13'E; 33°95'S). The term "conditioning" describes the process to induce gonad development, to the state of spawnability, in adult abalone outside of the normal

*Corresponding author. E-mail: sdaume@fish.wa.gov.au

spawning season. The conditioned broodstock were held indoors at a commercial abalone farm (Great Southern Marine Hatcheries, Albany, Western Australia-GSMH) for a period of 18–20 mo prior to this study. These animals were maintained in round plastic tubs (ca. 30 L volume) fitted with a central standpipe and airstones. The seawater was provided at a flow rate of $1-1 \times L \text{ min}^{-1}$ at constant water temperature of $17.0^\circ\text{C} \pm 0.2^\circ\text{C}$ ($\pm\text{SE}$). Animals were fed daily in excess with a formulated conditioning diet (Adam & Amos Foods Pty Ltd, South Australia). Conditioned broodstock were on average $137 \pm 7.2 \text{ mm}$ ($\pm \text{SE}$) in shell length and had a total weight of $461 \pm 67.4 \text{ g}$ ($\pm\text{SE}$). The wild caught broodstock were larger and averaged $169 \pm 2.9 \text{ mm}$ ($\pm\text{SE}$) and $745 \pm 45.9 \text{ g}$ ($\pm\text{SE}$).

Fatty Acid Composition of Broodstock Diets and Feed Intake

Samples of all abalone diets (seaweeds and formulated feed) were taken during the study and the fatty acid composition determined. Feed intake of the conditioned broodstock was determined daily over a 2-mo period.

Egg Sample Collection and Preparation

Broodstock was induced to spawn with ultraviolet-irradiated water. Egg samples were collected from a routine operation at GSMH over 2 spawning seasons (1st season: November 2001 to January 2002, 2nd season: October 2002 to December 2002). Seven batches of conditioned and 12 batches of wild caught broodstock were compared. Two additional batches derived from selected conditioned female broodstock, previously fed on the formulated feed, were fed on a mix of red seaweed (*Champia parvula*, *Gracilaria flagelliformis*) or *Ulva australis* for 3 mo prior to spawning. Approximately 6 g wet weight of eggs (ca. 400,000 eggs) was collected per batch. Samples were filtered onto pre-weighed glass fiber filters (Whatman GF/C, 4.7 cm diameter) and washed 3 \times with 0.5 M ammonium formate to remove residual salts. Samples were labeled, frozen in liquid nitrogen, stored at -70°C and freeze-dried (Edwards Modulyo Model E2M-18).

Egg Diameter and Offspring Performance

The diameter (egg cytoplasm and vitelline layer) of 30 unfertilized eggs was measured under an inverted microscope at $\times 400$ magnification and averaged for each batch. Eggs were collected within 30 min after spawning started and measured immediately ca. 10–15 min after collection without using any fixative.

Fertilization and hatch rates, larval survival and estimates of settlement, as well as survival at 2-wk postsettlement were recorded for seven of these batches.

Fertilization

Eggs of each batch (1 female abalone) were fertilized with 5–10 sperm per egg for 15 min. Eggs were washed in filtered seawater for 15 min after fertilization to remove excess sperm and to avoid polyspermy. The fertilization rate of each batch was determined by counting the eggs that were dividing after 1 h (indicating that eggs have been successfully fertilized) in three 1-mL samples and expressing these as a percentage of total number of eggs in the batch.

Hatch Rate

Eggs of each batch were placed into separate hatch tubs and formed a monolayer on the bottom of the tub. All tubs were set up

with low water flow and low aeration. The water was turned off ca. 2 h before hatch out started. The hatch rate (expressed as percentage) was determined by counting the number of unhatched eggs in three 1-mL samples, calculating the total of unhatched eggs, and subtracting these from the total number of successfully fertilized eggs.

Larval Survival

Larvae were reared in 300-L conical fiberglass tanks at a stocking density of up to 20 larvae per milliliter. All tanks were set up with low aeration and water flow after the larval shell was completely formed. The survival at the end of the larval rearing period (ca. 6 days at 18°C) was determined by counting the number of larvae in three 1-mL samples at the time of settlement multiplied by the total volume of the larval tank and dividing them by the total number of larvae successfully hatched.

Settlement

Larvae were settled on commercially used PVC settlement plates (40 \times 60 cm) covered by *Ulva lens*, which was cultured on the plates for 2–3 wk prior to larval settlement. Larvae were released into each of three semicommercial fiberglass tanks at a standard density of 100,000 (0.2 larvae ml^{-1}). Settlement tanks were ca. 490 L and set up with three baskets holding 20 settlement plates each. Settlement rate of each batch was determined 48 h after larval release. The term "settlement" describes the permanent attachment of the larvae to the substrate after shedding of the velum to complete metamorphosis. Postlarvae were counted again after 2 wk to determine their survival.

Fatty Acid Analyses

Samples (abalone eggs and diets) were analyzed at the State Chemistry Laboratory, Werribee, Victoria, Australia. Lipid was extracted from the samples using a modified Bligh Dyer method (Bligh & Dyer 1959). The fatty acid profiles were determined by gas chromatography (Varian Model 3400) with a BPX-70 column (SGE Australia) on the methyl esters of the extract from each sample.

Data Analyses

Statistical analyses were carried out using the STATISTICA 6.1 (Stat Soft, Inc. 2002) computer package. The assumptions of normality and homogeneity of variance were confirmed graphically for each data set using boxplots. Egg diameter, moisture, and lipid content of eggs spawned from conditioned and wild caught broodstock during both spawning seasons were compared with a two factor ANOVA with spawning season and conditioned or wild broodstock as fixed factors. Egg sizes and moisture content of unfertilized and fertilized eggs were compared with a *t*-test. *T*-tests were also used to compare individual PUFA and PUFA ratios between eggs from wild and conditioned broodstock. Relationships between the broodstock shell length and weight and egg diameter and batch size, as well as egg characteristics, and the performance of the larvae were explored using simple regression analyses.

RESULTS

Fatty Acid Composition of Broodstock Diets and Feed Intake

Fatty acid composition of abalone diets (seaweeds and formulated feed) is given in Table 1. The formulated feed is lower in

TABLE 1.

Fatty acid composition (%) of different abalone diets used in this study.

saturated fatty acids (SFA) than all algal samples. The formulated feed is higher in monounsaturated fatty acids (MFA) than the red algae *Champia parvula* and *Gracilaria flagelliformis* and the green alga *Ulva australis*. The total amounts of PUFA are highest in the red alga *Gracilaria flagelliformis*, followed by the formulated feed and the other algal diets. The relative amounts of PUFAs varied significantly. Formulated feed is high in linoleic acid (18:2n-6) and low in ARA (20:4n-6), whereas both red and green seaweed is low

in linoleic acid. The red seaweeds, especially *Gracilaria flagelliformis*, are high in ARA.

Feed intake of the conditioned broodstock, feeding on a dry formulated feed, was estimated to be $0.10 \pm 0.03\%$ body weight per day. Broodstock feeding on *Ulva* sp. or a mix of red seaweed (*Champia parvula*, *Gracilaria flagelliformis*) were consuming ca. $1.05 \pm 0.08\%$ (\pm SE) or $0.96 \pm 0.08\%$ (\pm SE) of their body weight per day respectively.

Egg Diameter, Batch Size, Proximate Analyses

The egg diameter, number of eggs per batch, weight ($\mu\text{g ind}^{-1}$) and proximate composition of abalone eggs derived from conditioned and wild broodstock are displayed in Table 2. There were no significant differences in average diameter of the eggs from conditioned broodstock ($199.6 \pm 2.5 \mu\text{m}$) and the batches of wild caught broodstock ($199.2 \pm 3.1 \mu\text{m}$), the percentage moisture of the eggs ($90.1 \pm 0.7\%$, $88.6 \pm 0.8\%$ respectively), or the total lipid of the eggs ($231.2 \pm 17.8 \text{ mg g}^{-1}$, $212.8 \pm 20.2 \text{ mg g}^{-1}$ respectively) (Table 3A). There was, however a significant difference between the two spawning seasons in egg diameter and total lipid, but not the moisture of abalone eggs (Table 3A). Eggs were larger during the second season compared with the first spawning season ($204.0 \pm 2.3 \mu\text{m}$, $193.5 \pm 2.4 \mu\text{m}$ respectively, Table 2), but had less total lipid ($178.9 \pm 12.4 \text{ mg g}^{-1}$, $276.8 \pm 10.4 \text{ mg g}^{-1}$ respectively). However, batches were larger during the first spawning season, particularly from conditioned broodstock. There was a significant correlation between broodstock shell length and weight and batch size across the two spawning season (Table 4) indicating that larger broodstock are more fecund. A significant relationship between broodstock shell length or weight and egg diameter was not detected.

Conditioned eggs were significantly heavier with more moisture than eggs derived from wild caught broodstock but had similar amounts of lipid (Table 3B, Table 2). Eggs derived from conditioned and wild broodstock, collected during the second spawning season, were heavier (dry weight) with no significant difference in moisture or lipid (Table 3B, Table 2). The percentage moisture and percentage lipid per egg (% of individual egg weight) were significantly higher during the first spawning season (Table 3C) with lower % lipid per egg in eggs from wild broodstock spawned during the second season (Table 2). Fertilized eggs were 5-10 μm larger than unfertilized eggs ($t = 2.24$, $P = 0.049$) and usually contained more moisture (Table 5, $t = 2.49$, $P = 0.03$).

Fatty Acid Analyses

Relative amounts (%) of fatty acids in eggs derived from conditioned and wild caught broodstock are presented in Table 6A and 6B respectively. Saturated fatty acids comprised on average 32% of total fatty acids in conditioned and 34% in eggs of wild broodstock, monounsaturates (MFA) made up 47% of conditioned eggs and 45% of eggs from wild broodstock whereas PUFAs were present only at 12% (5% and 7% for short and long chain PUFA) and 9% (1% and 7% for short and long chain PUFA) in conditioned and wild broodstock eggs respectively (Table 6A, 6B). The ratio of n-3/ n-6 PUFA of 1.5 was significantly lower in eggs of conditioned broodstock than the 2.1 ratio in eggs of wild caught broodstock ($t = -2.6$, $P = 0.02$). Similarly, the ratio of ARA to eicosapentaenoic acid (EPA) was significantly lower in eggs of conditioned broodstock than from wild broodstock (0.4 and 0.8 respectively; $t = -4.68$, $P < 0.001$).

Palmitic acid (16:0) was the dominant saturated fatty acid and

TABLE 4.

Correlation between broodstock shell length and weight and egg diameter and batch size.

Significant effects are shown in bold and italics ($n = 12$).

oleic acid (18:1) the dominant monounsaturated fatty acid in eggs of both wild caught and conditioned broodstock. The dominant PUFA was EPA (20:5n-3) for both conditioned and wild broodstock derived eggs. ARA (20:4n-6) was present in significantly higher proportion in eggs of wild caught broodstock ($t = -6.24$, $P < 0.001$), linoleic acid (LOA, 18:2n-6), linolenic acid (LNA, 18:3n-3) and decosahexaenoic acids (DHA, 22:6n-3) were significantly more abundant in eggs of conditioned broodstock ($t = 5.99$, $P < 0.001$; $t = 3.11$, $P = 0.006$, $t = 2.58$, $P = 0.02$ respectively). The relative amount of ARA was more than twice as high in wild broodstock, whereas the eggs of conditioned broodstock showed 10 times more of the LOA. Batch 7 was derived from broodstock that had been feeding on formulated feed for a period of 3.5 mo only and showed intermediate levels of both ARA and LOA. Two samples (Batch 15 and 18) were derived from conditioned female broodstock that had been transferred from a formulated diet onto red or green seaweed 3 mo prior to spawning (Table 6A). Eggs from broodstock that had been feeding on *Ulva australis* showed intermediate levels of LOA and similar levels of ARA when compared with the eggs derived from conditioned broodstock. Eggs from red seaweed-fed broodstock showed intermediate levels of

* Batch 7 derived from broodstock, which was only conditioned for a period of 3.5 months.

** Batch 15 and 18 derived from broodstock, which were conditioned on formulated feed but fed seaweed for 3 months prior to spawnings: batch 15 fed red seaweeds, batch 18 fed *Ulva* sp.

LOA and levels of ARA similar to eggs derived from wild caught broodstock.

Offspring Performance

The results of larval and postlarval performance of seven selected batches are shown in Table 7. The hatch rate was usually higher during the first spawning season, the best larval survival and overall survival was obtained from offspring derived from one female broodstock that was conditioned on formulated feed but was fed red seaweed for 3 mo prior to spawning during the second spawning season (Batch 15).

Correlation analyses were undertaken for all combinations of egg characteristics and the performance of the larvae (Table 8). There were strong and significant negative correlations between egg diameter and total lipid content ($r = -0.89$), between egg diameter and hatch rate ($r = -0.93$), and a positive correlation between total lipid content of the eggs and hatch rate. There was a strong negative correlation between the percentage moisture of the eggs and the performance at settlement ($r = -0.95$). There was also a positive correlation between the survival of the larvae during larval rearing and the survival of the postlarvae 2 wk after settlement ($r = 0.99$).

DISCUSSION

This study showed high variability in diameter, weight, and biochemical composition of abalone eggs between spawning seasons. In addition, the total number of eggs per batch declined during the second spawning season particularly in batches spawned from conditioned broodstock. However, broodstock spawned during the second season were slightly smaller. Overall animals were spawned on average 1 mo earlier during the second spawning season compared with the animals spawned during the first spawning season. Both could have contributed to the smaller batch sizes during the second season and the observed differences in moisture and lipid between the two spawning seasons. Other studies have established that temperature and conditioning intervals influence egg production of greenlip and blacklip abalone (Plant 2002, Grubert & Ritar 2003). Shepherd et al. (1992) demonstrated a relationship between broodstock size and fecundity of six wild populations of *Haliotis laevis*. In this study we found a positive correlation between broodstock size and weight and the batch size of spawned eggs.

Compared with the proximate composition of *Haliotis rubra* eggs from the wild (Litaay et al. 2001), *Haliotis laevis* eggs in this study were about two to three times heavier containing 10% to

15% more moisture and ca. 10% more lipid per egg during the first spawning season but similar amounts during the second spawning season. The difference in moisture between eggs of these studies might be partially explained by differences in time elapsed be-

tween spawning and measuring of the eggs (e.g., eggs might have been more hydrated). In this study, special care was taken that samples were measured approximately at the same time and no fixative was used. However, differences in total lipid cannot have been influenced by different sampling techniques. Total lipid expressed in mg g^{-1} was not given in the study by Litaay et al. (2001). Total lipid (mg g^{-1}) of digestive gland tissue of the abalone *Haliotis fulgens* (Nelson et al. 2002) was, however, much lower than total lipid in eggs of the abalone *H. laevis* determined in this study. Nelson et al. (2002) determined the lipid content of

Significant effects are shown in bold and italics ($n = 7$).

gonad tissue over a 1-y period and showed variations between 18 and 101 mg g⁻¹. In this study we collected eggs during two concurrent natural spawning seasons of *H. laevigata* and noticed significant differences between the two spawning seasons in both eggs derived from conditioned and wild broodstock with total lipid as low as 118 mg g⁻¹ (1st spawning season) and as high as 350 mg g⁻¹ (2nd spawning season). Egg samples were taken earlier in the season during the second spawning season, the sampling started in early October and finished in December with most of the samples collected during October to November 2002. Samples during the first spawning season were mainly taken during December 2001 and January 2002. It is conceivable that eggs were not quite as mature during the second spawning season and thus smaller than during the first spawning season. Further studies are needed to establish the relationship between egg size, biochemical composition, and maturity of abalone eggs.

Nelson et al. (2002) demonstrated that C₂₀ PUFA in the digestive gland can vary between seasons and that variations over the year coincided with variation in their macroalgal diet. Similarly, Dunstan et al. (1996) found elevated levels of short chain linoleic acid (LOA) and reduced levels of ARA (ARA, 20:4n-6) in juvenile abalone feeding on formulated feeds, despite the fact that the formulated feed contained high proportions of the ARA precursor LOA (18:2n-6). Australian species of abalone have a preference for red seaweed such as *Gracilaria* spp. (Shepherd & Steinberg 1992), which are rich in the PUFAs, ARA, and EPA (Mai et al. 1996, Dunstan et al. 2000, Table 1). A formulated feed used in Australia, however, is low in ARA (Dunstan et al. 1996, Table 1). Results of the present study indicate that the PUFA composition of the broodstock diets influenced the PUFA profile in abalone eggs. Eggs derived from wild caught broodstock were higher in ARA, the formulated feed used is high in LOA (Table 1), and eggs from broodstock feeding on this formulated feed showed a much higher level of this PUFA. In accordance with our findings, Soudant et al. (1996) showed that the PUFA composition of the diets influenced the PUFA profiles in eggs of the great scallop. Results of our study also indicate that 3 mo of feeding on an altered diet is sufficient to alter the fatty acid profile of the eggs. Notably the progeny from one particular batch of formulated diet fed conditioned broodstock that was transferred onto a red seaweed diet showed the best performance.

Arachidonic acid is essential for marine fish (Sargent et al. 1999), and until recently the importance of this fatty acid had been largely overlooked (Bell & Sargent 2003). Whether ARA is essential to abalone needs to be examined (Dunstan et al. 1996). However, Dunstan et al. (2002) demonstrated that most of the final tissue ARA originated from dietary linoleic acid (LOA) and, because formulated feed contains large amounts of this fatty acid, they concluded that it is unlikely that ARA is limiting in abalone. Although high levels of ARA may not be required for muscle growth, it may be required for ovogenesis and embryogenesis. ARA is a major precursor of prostaglandins, which influence reproduction in molluscs (Osada et al. 1989). There is growing evidence that ARA is important in reproduction of marine fish (Bell & Sargent 2003) and Soudant et al. (1996) demonstrated that DHA, EPA, and ARA were preferentially incorporated into the polar lipid fraction of scallop eggs. They suggested that the higher levels of ARA in eggs than in larvae of the scallop indicated its specific role during ovogenesis. Recently, Nelson et al. (2002) showed that ARA was markedly lower in the digestive gland than in the foot tissue of the abalone *Haliotis fulgens* and concluded that this fatty acid may have been converted to prostaglandins, which

indicates its function in gametogenesis. In accordance with our findings, Dunstan et al. (1996) reported that ARA was present at 0.4% in formulated diets and at 1.1% in the macroalga *Ulva australis*. These results together with our findings indicate that ARA was preferentially incorporated into the eggs of broodstock feeding on formulated feed and *Ulva australis*. In our study, the levels of ARA were higher in eggs than in the respective diets of the broodstock, except of the *Gracilaria* diet. In addition, several authors have indicated that beyond this, certain fatty acids play a vital role in determining the success of metamorphosis in bivalves (Helm et al. 1973, Kraeuter et al. 1982, Wilson et al. 1986). Abalone have lecithotrophic larvae, which cannot digest particles but are able to take up nutrients from seawater (Jaekle & Manahan 1989). Consequently the lipid of the eggs must fuel major parts of the energetics of larval metamorphosis. Jensen et al. (1990) showed that the metamorphosis of *H. rufescens* larvae was influenced by free fatty acids, especially ARA. A very low relative amount of PUFAs compared with SFA and MUFA was found in the abalone eggs. On average, PUFAs contributed only 10% of the total fatty acid pool. In contrast, Soudant et al. (1996) demonstrated that up to 50% of the fatty acids were PUFAs in scallop eggs. PUFAs in abalone diets (algal diets and formulated feed) on the other hand, contribute about 35% to 56% but this was not reflected in the eggs. Nelson et al. (2002) showed high variability in relative amounts of PUFAs in digestive gland tissue of *H. fulgens* between seasons and diets, ranging between 7% and 42%. In this study, however, the relative proportions of saturated, monounsaturated, and PUFAs in eggs of the abalone *H. laevigata* were very consistent in all samples regardless of the broodstock diet probably because of the metabolic necessity to maintain equilibrium between these fatty acid groups. It is conceivable that SFA and MUFA are stored in abalone eggs and used as an energy source for the developing larvae.

Correlation analyses indicated that smaller eggs had higher lipid content and that larvae from these batches hatched better; larvae hatching from eggs with lower moisture content performed better at settlement.

The results of this study demonstrate high variability in proximate biochemical composition and fatty acid profiles of abalone eggs between batches derived from conditioned and wild broodstock as well as between two consecutive spawning seasons. Our preliminary results provide initial evidence that biochemical composition of abalone eggs are influenced by the broodstock diets and these in turn may affect the performance of the progenies. The results related to offspring performance have to be treated carefully because only seven batches were compared during the two spawning seasons. Further work is planned to provide more information on egg provisioning and offspring performance in relation to the composition of the broodstock diets, particularly in relation to fatty acid content. If abalone aquaculture is to become more advanced and sustainable, broodstock have to be successfully conditioned on farms to secure high quality eggs and larvae, because this will enable selective breeding programs for a further development of the industry.

ACKNOWLEDGMENTS

The authors thank the staff for their help and support during spawnings and Dr Greg Maguire, Dr Brett Glenecross, and Dr Sagiv Kolkovski for their helpful comments. Great Southern Marine Hatcheries in Albany, Western Australia hosted this experiment.

SETTLEMENT OF ABALONE (*HALIOTIS IRIS*) LARVAE IN RESPONSE TO FIVE SPECIES OF CORALLINE ALGAE

RODNEY D. ROBERTS,^{1, 2,*} HEINRICH F. KASPAR¹ AND RICHARD J. BARKER³

¹Cawthron Institute, Private Bag 2, Nelson, New Zealand; ²Department of Marine Science, University of Otago, P.O. Box 56, Dunedin, New Zealand; ³Department of Mathematics and Statistics, University of Otago, P.O. Box 56, Dunedin, New Zealand

ABSTRACT Abalone recruits are found predominantly on crustose coralline algae (CCA) and recruitment seems to vary among coralline species or growth-forms. Spatial patterns in the recruitment of marine invertebrates can be formed by processes acting before, during, or after settlement. This study used laboratory experiments to examine the settlement of *Haliotis iris* larvae on five species of CCA. When the CCA species were presented individually to larvae, all induced >88% of larvae to attach within 1 day, and >80% to metamorphose within 3 days. When given a choice of the five CCA, larvae settled most on *Pneophyllum coronatum* and *Hydrolithon rupestris*, and settled least on *Mesophyllum pritzianum*, *Phymatolithon repandum*, and *Lithophyllum carpophylli* gave intermediate results. The speed of metamorphosis in the no-choice experiments mirrored the species preferences in the choice experiments, with metamorphosis occurring most rapidly on *Pneophyllum coronatum* and *Hydrolithon rupestris*. The two preferred species were thin crusts, whereas the two least preferred species formed thick, morphologically complex crusts. In a choice experiment, the proportion of larvae choosing a CCA specimen showed no correlation with bacterial density ($r = -0.25$, $P = 0.52$, $n = 25$), but a weak positive correlation with diatom density ($r = 0.52$, $P = 0.02$, $n = 25$). However, diatom densities were low on all CCA species, and are unlikely to be a primary cause of settlement preference. It is hypothesized that at least some of the variation in recruitment among CCA species or growth forms observed in the wild is determined by selective settlement.

KEY WORDS: abalone, biofilm, coralline algae, larval settlement, metamorphosis, recruitment.

INTRODUCTION

Patterns of recruitment in marine larvae may be caused by processes occurring before, during, or after settlement (Connell 1985). The relative importance of these stages in determining recruitment varies among species and locations (e.g., Keough & Downes 1982, Connell 1985, Gaines & Roughgarden 1985, Woodin 1986, Rowley 1989, McShane 1992, Stoner et al. 1996, Walters & Wetley 1996, Mundy & Babcock 2000).

Abalone recruits are found almost exclusively on crustose coralline algae (CCA) (Shepherd & Turner 1985, McShane & Smith 1988, Day & Branch 2000). Based on this selection of a particular habitat it was initially suggested that differential postsettlement mortality is unlikely to be important in determining abalone recruitment (McShane 1991, McShane 1992). However, the broad grouping "crustose coralline algae" includes a wide range of species and growth forms (Woelkerling et al. 1993). Recent research on abalone ecology has recognized this complexity and demonstrated that the species and growth form of CCA can influence the number of abalone recruits (McShane 1996, Shepherd & Daume 1996, Daume et al. 1999, Day & Branch 2000). In South Australia, "lumpy" and "uneven encrusting" growth forms had more recruits of *Haliotis laevigata* and *Haliotis scalaris* than other coralline growth forms (Shepherd & Daume 1996) and in South Africa, "knobbly" corallines contained the highest densities of *Haliotis midae* recruits (Day & Branch 2000).

Such patterns could be caused by selective settlement or differential postsettlement survival. Work to date has focused on the latter. It has been suggested that morphologically complex CCA growth forms may be more suitable than flat crusts because they provide greater protection of postlarvae from wave shear (postulated by McShane & Naylor 1995 and McShane 1996, but not supported by experimental evidence of Naylor & McShane 1997a) inadvertent ingestion (Fletcher 1987, McShane 1991), predatory

fish (McShane 1996) or because they protect pockets of microbial food from access by larger grazers (Shepherd & Daume 1996, Day & Branch 2000). On the other hand, topographically complex surfaces may increase the thickness of the diffusive boundary layer by impairing water movement near the substrate, resulting in more extreme fluctuations in water chemistry in the postlarval environment (Kaspar 1992, Day & Branch 2000). Morphologically complex CCA growth forms generally grow as thick crusts. These harbor predatory worms that can decimate populations of newly settled abalone (Morse et al. 1979, Naylor & McShane 1997a, Naylor & McShane 1997b).

Coralline algae are among the most effective larval settlement cues for all species of abalone tested to date (Roberts 2001a). Other natural surfaces such as biofilms can induce larval metamorphosis, but few approach the speed and consistency of CCA (Roberts 2001a, Roberts 2001b). Little work has been done on the extent to which settling abalone larvae discriminate among coralline species or growth forms.

Discrimination among substrata is well demonstrated for settling marine invertebrate larvae (reviewed by Crisp 1974, Pawlik 1992, Rodriguez et al. 1993). Some studies have demonstrated settlement preference in multiple choice experiments (e.g., Kirchner et al. 1982, Miron et al. 1996, Stoner et al. 1996, Wiecezorek & Todd 1997, Snelgrove et al. 1998, Daume et al. 1999). These choice experiments test the relative preference of larvae for a particular substrate when faced with a range of options, whereas experiments that present cues individually test the absolute inducing ability of a substrate for larvae that are given no other option. The former is more relevant to the situation faced by a larva in nature.

The few data available for abalone larvae provide conflicting evidence on selectivity among types of CCA. Morse et al. (1980) and Morse and Morse (1984) reported equally strong settlement in response to various species of CCA, but the species were presented individually rather than as multiple choices. In contrast, larvae of *Haliotis laevigata* metamorphosed in greater numbers on the thick,

*Corresponding author. E-mail: rodney.roberts@cawthron.org.nz

lumpy crusts of *Sporolithon durum* than on the encrusting *Hydrolithon rupestre* (= *Hydrolithon rupestris*) or the warty *Mesophyllum engelhartii* (Daume et al. 1999). Larvae also metamorphosed more quickly on *Sporolithon* with a lumpy growth form than the same species with an encrusting growth form. Both patterns were consistent in choice and no-choice experiments.

Data comparing the performance of types of CCA for the settlement of invertebrates other than abalone are also sparse. The scleractinian coral *Agaricia agaricites humilis* metamorphosed strongly in response to only 3 of 6 CCA species presented individually (Morse et al. 1988). The soft coral *Acyonium siderium* metamorphosed in response to both of two CCA species (Sebens 1983).

More data are required to assess the importance of settlement preferences in determining distributions of recruits among types of CCA. The ecological justification for such studies is compelling. CCA are abundant from tropical to polar waters (Johansen 1981, Steneck 1986) occupying more hard substratum within the photic zone than any other organism (Steneck & Paine 1986). CCA trigger the settlement of numerous species of marine invertebrate larvae (Pawlik 1992, Johnson et al. 1991) and difficulties with the taxonomy and identification of CCA have obscured the species specificity of many interactions involving CCA (Steneck & Paine 1986).

The present study compares abalone larval settlement on 5 CCA species with diverse growth forms, in choice and no-choice experiments. It was found that all CCA species induced metamorphosis if presented individually, but that larvae exhibited preferences when given a choice.

METHODS

Larval Rearing and Bioassays

Ripe adult *Haliotis iris* Gmelin 1791 were spawned by the hydrogen peroxide technique (Morse et al. 1977) and the larvae reared in flowing seawater as described previously (Roberts & Nicholson 1997) until taken for assays. Competent larvae were added to the wells of tissue culture plates (Falcon 3043 or 3047) containing CCA in 2 mL (no choice experiments) or 3.3 mL (choice experiments) of 0.2 μm -filtered seawater with 150 $\mu\text{g}/\text{mL}$ of both penicillin G sodium (Sigma) and streptomycin sulphate

(Sigma). Assay plates were wrapped in foil and incubated at 17 ± 0.5 C. To quantify settlement, the whole of each CCA fragment and its well were examined microscopically (Roberts & Nicholson 1997) after -1 and 2.5 to 3 days of incubation. Counts were converted to percentage of larvae showing: (a) "shell growth" (velum shed and peristomal growth visible); (b) "metamorphosis" (velum shed, with or without shell growth); and (c) "attached" (metamorphosed or attached by foot). "Settlement" is used as a general term encompassing larval attachment and metamorphosis (Roberts 2001a). Negative controls of filtered seawater (with clay in Experiment 3) showed 0% to 0.3% metamorphosis within 3 days (data not presented). Experimental details are presented in Table 1.

Collection and Preparation of CCA

Details and taxonomic authorities of the five CCA species used are given in Table 2. Fragments of ~ 0.15 to 0.3 cm^2 "floor area" (defined later) were prepared by cutting the plastic on which they were growing (for the fragile *Pneophyllum coronatum* and *Hydrolithon rupestris*) or breaking off fragments of the plant with a knife (*Lithophyllum carpophylli* and *Mesophyllum printzianum*) or a hammer and chisel (*Phymatolithon repandum*). Each assayed fragment was from a separate plant, and each plant of *Lithophyllum carpophylli* was from a separate host plant of *Carpophyllum maschalocarpum*.

In Experiments 1 and 3 the fragments of CCA were held in filtered seawater for <30 min before being moved into bioassay chambers. In Experiment 2, fragments were soaked in $\sim 1\text{L}$ of static $1\text{-}\mu\text{m}$ filtered seawater for 4 days at 17°C before bioassay, with the intention of removing dissolved components leaking from broken edges of the CCA. This holding period without grazers would also alter the biofilm on the CCA (not quantified). In Experiment 3, the floor of each bioassay chamber was filled with a flattened plug of "colour clay" (Trident Toy Co. Ltd, Hutton, Avon, England) to ~ 2.5 mm depth and the CCA fragments embedded in the clay so that their upper (live) surface was flush with the surface of the clay. The clay was molded to fit closely the edges of the samples. The intention of this treatment was to make all CCA species equally accessible to crawling larvae (see also Discussion).

For choice experiments, the five CCA fragments in a replicate were randomly placed in a circle on a radius two-thirds that of the

TABLE 1.

Details of experiments conducted during this study. Start date is the day on which larvae were added to CCA. Larval stage was determined by the number of fully chitinized transverse rows of teeth on the larval radula (Tong and Moss 1992).

Experiment Number	Larval Batch; and Start Date	Larval Stage (Rows of Radula Teeth)	Number of Replicates	No. Larvae Per Well Mean \pm SE (n)	Purpose
Choice Exp. 1	1; 18/9/98	8-9	6	192 \pm 30 (6)	Determine relative settlement of larvae given a choice of five CCA species.
Choice Exp. 2	1; 22/9/98	12-13	6	211 \pm 27 (6)	Repeat Choice Exp. 1 but with CCA fragments soaked for 4 days to reduce effects from inducers leaking from damaged plants.
Choice Exp. 3	3; 21/4/99	7-8	6	92 \pm 8 (6)	Repeat of Choice Exp. 1 but with a separate batch of larvae and with CCA fragments embedded in clay to standardize their accessibility to crawling larvae.
No-choice Exp. 1	1; 18/9/98	8-9	5	58 \pm 5 (30)	Quantify settlement of larvae in response to the 5 CCA species presented individually for comparison with Choice Exp. 1.
No-choice Exp. 3	3; 21/4/99	7-8	6	43 \pm 5 (30)	As previous for comparison with Choice Exp. 3.

TABLE 2.

Morphologic and ecological features of the crustose coralline algae (CCA) used in this study.

CCA Species	Source	Morphology	Crust Thickness	Likely Grazers
<i>Pencophyllum coronatum</i> (Rosanoff) Penrose in Chamberlain	On plastic plates in GACL hatchery	Encrusting	~0.2 mm	Juvenile <i>Haliotis iris</i> and small crustacea
<i>Hydroolithon rupestre</i> (Foslie) Penrose	On plastic plates in GACL hatchery	Encrusting	~0.2 mm	Juvenile <i>Haliotis iris</i> and small crustacea
<i>Phymatolithon repandum</i> (Foslie) Wilks and Woelkerling	On stones from shallow subtidal at Cable Bay (173°24'E, 41°11'S)	Encrusting to warty	~0.5 mm	Mixture of grazing species but not abalone

<i>Mesophyllum printzianum</i> Woelkerling and Harvey	On stable boulders in sublittoral fringe on shore by GACL	Warty to fruticose	2–5 mm	Mixture of grazers including <i>Haliotis iris</i>

GACL = Glenhaven Aquaculture Centre Ltd (174 21.2'E, 41° 11.4'S). Morphology terminology follows Woelkerling et al. (1993).

tissue culture plate well (Falcon 3043), with the center of the well unoccupied. For no-choice experiments the CCA fragment was placed in the center of the tissue culture plate well (Falcon 3047) with species randomly arranged in the plates.

Phymatolithon repandum and *Mesophyllum printzianum* have uniporate gametangial conceptacles and multiporate tetrasporangial conceptacles, making these life cycle stages easy to distinguish. A previous experiment showed that both life cycle stages induced equally strong larval attachment and metamorphosis within 60 h (data not shown), so life cycle stage of CCA was excluded from further consideration.

For Choice Experiment 1, fragment size was estimated by measuring length and width of fragments with an eye-piece micrometer in a binocular microscope. In Experiment 3, the size of CCA fragments was determined by image analysis (Optimas 6) of video-records. Fragment size was measured as the area of the CCA when viewed from above (= "floor area"), taking no account of the greater surface area of the topographically complex corallines (notably *Mesophyllum printzianum*). The floor area measurement was regarded as the most appropriate measure of "target size" (see Discussion).

Scanning Electron Microscope Analysis of Biofilms

Samples of coralline algae were prepared for scanning electron microscope (SEM) analysis by 2 methods. A simple preparation procedure (termed "SEM method 1") was designed to minimize loss of the microbial population on the CCA surface. A more complex procedure (termed "SEM method 2") was followed to preserve the form of microbes and other fine structures on the surface of the corallines.

SEM method 1: for each replicate in Experiment 3, a sample from the same plant was preserved in 2% glutaraldehyde (Merck) then air dried in a laminar flow cabinet. Dried samples were attached to aluminum stubs with double-sided carbon tape and silver paint then sputter-coated with gold/palladium before viewing with a Cambridge S360 Stereoscan SEM. On each sample, bacteria were counted in 12 × 5000 magnification fields of view (each 24 μm × 17 μm) and diatoms in 12 × 1000 fields of view (each 121 μm × 82 μm). Samples were scanned systematically, and nonoverlapping fields of view were haphazardly located

along the scan path. Additional samples of each CCA species, collected from the same locations, were fixed in 4% formalin in seawater, air dried, sputter coated, and viewed with a Hitachi 5-2250N SEM. Diatoms were counted in 12 × 1000 fields of view (each 127 × 98 μm).

SEM method 2: Samples of each species of CCA from the same sources were placed directly into foil-wrapped containers with 2.5% glutaraldehyde in the field. A day later samples were transferred to 1% osmium tetroxide for 24 h, then desalinated with a graded series of 0, 25, 50, 75, and 100% distilled water in filtered seawater (15 min per step), dehydrated with a graded series of 10, 30, 50, 70, 90, 95, and 100% ethanol in distilled water (15 min per step), and critical point dried (Hayat 1989, Johnson et al. 1991). Samples were coated and scanned as earlier.

Statistical Analyses

Correlations were tested among planned comparisons using the Dunn-Sidak method to maintain the experiment-wise Type I error rate at 0.05 (SPSS Inc. 1999). Diatom and bacterial densities used in correlations related only to the surface of the CCA fragments, ignoring the surrounding surfaces. In data from the choice experiments, the ANOVA assumption of independent errors was violated—knowing that a larva settled on CCA species A also tells us that it did not settle on the other species, so the errors are correlated. Settlement preferences across the three replicated choice experiments were analyzed by fitting a log-linear model to the 3-way classification of CCA species (5 levels), experiments (3 levels), and replicates within experiments (6 levels). Only those animals that settled on CCA were used in the analysis, and it was assumed that the effects of day and replicate on settlement preference were additive rather than interactive (i.e., the 3 way interaction term was omitted from the model). The analysis used a quasi-likelihood approximation to an over-dispersed log-linear model, with random experiment and replicate effects (Link 1999). This approach treats the random effects as fixed effects, and assumes that larvae behave independently. This leads to an intentionally over-dispersed model, where the over-dispersion is caused by experiment and replicate effects and/or by nonindependent behavior among larvae. There is a corresponding intentional underestimation of the sampling variance and test statistics, which are

then adjusted using the quasi-likelihood adjustment factor (= ratio of goodness of fit statistic to its degrees of freedom) (Link 1999). Lack of a significant replicate effect after adjustment for over-dispersion (see Results) allowed the data to be reduced to a 2-way classification (5 CCA species, 3 experiments). To obtain selection probabilities for each CCA species, the data from the 3 experiments were combined by a weighted average that took into account the variance within each experiment (Burnham et al. 1987). The reported 95% confidence intervals include variance components from the estimation of the selection probabilities within experiments, and the between-experiment variation.

RESULTS

Experiments With a Choice of Coralline Species

In Choice Experiment 1, *Hydrolithon rupestris* and *Pneophyllum coronatum* attracted more than twice as many settling larvae as the other three CCA species (Fig. 1A). Few larvae (0.7% of total) settled on *Mesophyllum printzianum*. Almost all of the larvae had metamorphosed, and most had begun to grow postlarval shell, within 22 h. Nearly half of the larvae were found on the floor or walls of the assay chamber, rather than on the CCA themselves (Fig. 1A). Fragment size was almost identical in four of the CCA species (averages of 0.194 to 0.197 \pm 0.02 cm²) whereas the most preferred species for settlement, *Hydrolithon rupestris*, had slightly smaller fragments (0.15 \pm 0.03 cm²).

In Choice Experiment 2 the order of preference for the CCA species was almost the same as in Choice Experiment 1 except that *Hydrolithon rupestris* was less preferred, slipping to second choice and comparable to *Phymatolithon repandum* (Fig. 1B). All larvae on CCA had metamorphosed, but of the 24% not on CCA, 8% had attached but not metamorphosed, and 7% had not yet attached (Fig. 1B). The proportion of larvae not on CCA was about half of that in Choice Experiment 1 (Fig. 1A).

In Choice Experiment 3, the order of preference for CCA species was again similar with *Pneophyllum coronatum* and *Hydrolithon rupestris* clearly preferred (Fig. 1C, D). *Phymatolithon repandum* was less preferred in this experiment than previously. Larvae were slower to metamorphose in this experiment, with 46% of larvae attached (mostly to CCA fragments) but not metamorphosed after 23 h. However, the majority of abalone found on the two preferred species, *Pneophyllum coronatum* and *Hydrolithon rupestris*, had metamorphosed within 23 h. The size of CCA fragments varied little among the CCA species (Fig. 2C), and showed no correlation with the proportion of settlers ($r = 0.02$, $P = 0.999$, $n = 30$).

Analysis of the data from the three choice experiments demonstrated a strong difference in settlement probabilities among CCA species ($F_{12,40} = 17.55$, $P < 0.0001$). *Pneophyllum coronatum* and *Hydrolithon rupestris* attracted significantly more settlers than the other CCA species (Fig. 3). The goodness-of-fit statistic from the model omitting the 3-way interaction term provided evidence of over-dispersion ($\chi^2_{40} = 174.27$, $p < 0.001$) indicating that either substrate settlement probabilities varied among experiments and/or replicates, or that larvae were not behaving independently. After accounting for over-dispersion, there was little evidence of variation between replicates ($F_{20,40} = 1.192$, $p = 0.31$) but strong evidence of variation in settlement probabilities between days ($F_{8,40} = 3.081$, $p = 0.008$).

Biofilms on Coralline Species

The proportion of larvae choosing a CCA specimen in Choice Experiment 3 showed a weak positive correlation ($r = 0.52$, $P = 0.02$, $n = 25$) with the density of diatoms on that plant (Fig. 2A). In contrast, the proportion of settling larvae showed a nonsignificant negative correlation ($r = -0.25$, $P = 0.52$, $n = 25$) with the density of bacteria (Fig. 2B). Bacterial and diatom densities varied greatly between plants within species and between quadrats within plants. Mean diatom densities were low, ranging from zero to only 3×10^4 cm⁻² (Fig. 2A, Table 3). Bacterial densities ranged from 0.2 to 8×10^6 cm⁻² (Fig. 2B).

On *Mesophyllum printzianum* there were clearly demarcated areas with either few bacteria and little surface polysaccharide, or many bacteria among copious polysaccharide (Fig. 4A to D). Diatoms were seen only as one patch on one of the five *Mesophyllum printzianum* plants examined. *Mesophyllum printzianum* previously collected from the same location had dense patches of diatoms in grazing refugia beside protruberances or in sunken conceptacle pore-plates (Fig. 4 E, F). However, searching with SEM confirmed the absence of such patches of diatoms on the plants used in this Choice Experiment 3.

Lithophyllum carpophylli from Experiment 3 also showed biofilm patchiness on a scale of hundreds of micrometres. Bacteria were much more abundant in the cavities formed by cells that had lost their exterior wall (Fig. 5A). Few bacteria were seen on areas of thallus where the external wall of the cells was flush with the thallus surface (no cell cavities present). However, on another occasion this did not hold true (Fig. 5B). No diatoms were seen on the plants of *Lithophyllum carpophylli* used in Choice Experiment 3, either in the 60 diatom quadrats (Fig. 2A), or in visual scanning the plants with SEM. On another occasion, variable densities of diatoms were found on this CCA species (Table 3).

Bacteria were several times less abundant on *Phymatolithon repandum* than on the other coralline species (Figs. 2B, 5C). The surface of this species typically had extensive fine debris that resulted from disintegration of the calcified lateral cell walls (Fig. 5C). Although this may obscure some bacteria from view, it was obvious that the bacterial density was low. Diatoms were found on only two of the five plants inspected, and the average diatom density was low (Fig. 2A). On other occasions, high diatom densities were seen on *Phymatolithon repandum*, but these appeared to be removed by epithallial sloughing (Fig. 5D). Extensive grazing marks were often visible on this species (Fig. 5E) and microbial densities were low in areas scarred by grazing.

Pneophyllum coronatum and *Hydrolithon rupestris* had variable densities of diatoms (Figs. 2A, B, Table 3) and bacteria (Fig. 5F, H). On *Pneophyllum coronatum* there were fewer microbes on young tissue close to the growing edge of the plant (Fig. 5G).

The diatom assemblage on most plants was dominated by *Cocconeis* spp., *Amphora* spp. and other naviculaoid diatoms (Table 3). On one occasion *Tabularia* sp. was abundant in grazing refugia on *Mesophyllum printzianum*.

No-choice Experiments With Coralline Species Assayed Individually

When the five species of CCA were presented individually to larvae, all induced a high proportion of larvae to attach and metamorphose. There were some differences in the timing of responses among CCA species and among experiments (Figs. 6, 7). Those species that induced metamorphosis most rapidly (*Pneophyllum coronatum* and *Hydrolithon rupestris*) (Figs. 6, 7) were the species preferred in the choice experiments (Figs. 1 and 3).

A) Choice Experiment 1: 22 hour counts

B) Choice Experiment 2: 19 hour counts

C) Choice Experiment 3: 23 hour counts

D) Choice Experiment 3: 69 hour counts

Figure 1. Settlement of larvae offered a choice of five CCA species. Locations are categorized as being on one of the coralline algal species, or "not on CCA". Settlement stages are defined as Unattached = larvae have not attached or metamorphosed; Attached only = larvae have attached but not metamorphosed; Metamorphosed = larvae have initiated metamorphosis by shedding the velum and may or may not have commenced postlarval shell growth. Confidence intervals apply to the totals for each category. Data are shown for three experiments. For experiment 3, counts were made after both 23 and 69 h of bioassay.

A) Diatom density

B) Bacterial density

C) CCA fragment size

Figure 2. Covariates measured for Choice Experiment 3. Fragment size is measured as the "floor area" covered by each CCA fragment. Diatom and biofilm densities were determined by SEM inspection of quadrats on fragments of the same plants used in settlement bioassays (see Fig. 1C, D).

In the first experiment, the mean percent metamorphosis within 20 h was $\geq 95\%$ on *Pneophyllum coronatum* and *Hydrolithon rupestris*, but only 57% on *Mesophyllum printzianum* and 68% on *Phymatolithon repandum* (Fig. 6A). By 60 h, most of the remaining larvae had metamorphosed (Fig. 6B). The same pattern was evident in No-choice Experiment 3, where metamorphosis occurred more slowly (Fig. 7A, B).

Movement off CCA

The animals that were not on CCA after 20–24 h were mostly unmetamorphosed (Fig. 8). The exception was in Choice Experi-

ment 1, where a large proportion of larvae were found metamorphosed, and not on CCA (Fig. 1A). By 2.5 to 3 days there was an increase in the total number of larvae not on CCA and a predominance of animals with postlarval shell growth, which had metamorphosed on CCA then migrated off (Fig. 8).

DISCUSSION

Strong Settlement on all CCA Species Tested

When presented individually, all five species of coralline induced over 80% of *Haliotis iris* larvae to metamorphose within 3

Figure 3. Probability of *Haliotis iris* larvae settling on each of the five CCA species when given a choice. Analysis used data from 1 day counts in Choice Experiments 1, 2, and 3. Pc = *Pneophyllum coronatum*, Hr = *Hydrolithon rupestris*, Pr = *Phymatolithon repandum*, Lc = *Lithophyllum carpophylli*, Mp = *Mesophyllum printzianum*.

days. There was variation in the speed of the response among CCA species, and between the two experiments (Figs. 5, 6) but all CCA species were effective inducers of metamorphosis. When presented with a choice of 5 CCA species, *Haliotis iris* larvae preferentially settled on certain species (Fig. 2), and the preferred species were those that induced metamorphosis most quickly in the no-choice experiments.

The strong settlement response of *Haliotis iris* larvae to all CCA tested contrasts with the major differences among CCA species reported for *Haliotis laevigata* (Daume et al. 1999) and a scleractinian coral (Morse et al. 1988), but is consistent with the response of *Haliotis rufescens* (Morse et al. 1980, Morse & Morse 1984) and a soft coral (Sebens 1983) to multiple CCA species.

Rejection Rates of CCA Underlie Settlement Preferences

Given that the chance of larval encounter is equivalent for the various CCA species (Fig. 2C), the existence of settlement preferences implies that larvae were more likely to reject certain species after contact. This preference was exercised even though all species were strong inducers of metamorphosis when presented alone (Figs. 6, 7). The more rapid metamorphosis seen on *Pneophyllum coronatum* and *Hydrolithon rupestris* in the no-choice experiments is consistent with the greater likelihood of larvae "accepting" these substrata when contacted by larvae.

Factors Controlling Acceptance or Rejection of CCA

There are various possible causes for the preferential settlement on certain CCA species. Some potential causes relate to factors that covary with CCA species, rather than being a function of the species itself.

The settlement preferences we observed could result from differences in the settlement-inducing chemicals of the different CCA species (McShane 1996). The specific chemicals involved, the quantities produced, or their availability at the surface of the plant could all vary within and among CCA species, but there is no direct evidence to support or refute this. The recent identification of an abalone metamorphosis-inducing molecule from a CCA (Suenaga et al. 2004) provides an analytical target to begin exploring this question.

The biofilm on CCA is a potential determinant of settlement inducing activity (Johnson et al. 1991, Johnson & Sutton 1994). In the present study, the proportion of larvae choosing a CCA speci-

men showed no correlation with bacterial density, but a weak positive correlation with diatom density. The density of diatoms on CCA was generally low, with even the highest densities barely reaching levels known to induce high levels of abalone larval attachment (Kawamura & Kikuchi 1992, Roberts 2001a). However, diatoms can combine synergistically with other cues (Roberts & Nicholson 1997, Roberts 2001a) and the densities required to be effective in such a synergism might be much lower.

There was a relationship between the morphology of the corallines and the settlement preferences in choice experiments. The two most preferred species (*Pneophyllum coronatum* and *Hydrolithon rupestris*) were both thin encrusting corallines, the intermediate choice (*Phymatolithon repandum*) was a slightly thicker encrusting to warty growth form, whereas the two least preferred species (*Lithophyllum carpophylli* and *Mesophyllum printzianum*) were thick crusts (Table 2). It is interesting to consider whether these choices might make any ecological sense. Thick crusts of *Mesophyllum printzianum* occur on stable rock substrata (Table 2, Naylor & McShane 1997a) whereas the thin encrusting *Pneophyllum coronatum* and *Hydrolithon rupestris* seem to be opportunistic species (author's personal obs.), such as found on mobile rocks in shallow water (McShane 1996, Naylor & McShane 1997a). Experimental evidence shows that the thick-crust *Mesophyllum printzianum* hosts polychaete predators that kill many recently settled abalone (Naylor & McShane 1997a, Naylor & McShane 1997b) and that its surface topography offers no demonstrable protection from dislodgement of *Haliotis iris* postlarvae by wave shear (Naylor & McShane 1997b). Juvenile *Haliotis iris* (10–70 mm shell length) are found during daylight hours under rocks that have undersides free of bulky encrusting organisms (McShane et al. 1995, author's personal obs.). Such rocks are somewhat mobile, occur in shallow water and are commonly colonized by thin crusts of CCA (McShane 1996, Naylor & McShane 1997a) similar to *Pneophyllum coronatum* and *Hydrolithon rupestris*. McShane (1996) remarked on the low frequency of *Haliotis iris* recruits on thick growth forms of CCA and suggested that lower concentrations of settlement inducers or the presence of predatory polychaetes were possible causes. Thus the preference for thin crusts that we observed in *Haliotis iris* larvae has potential benefits for both postlarvae and cryptic juveniles, though the suggestion of any link is merely speculative.

There has been some discussion about the effect that CCA growth form has on the biofilm present. Morphologically complex growth forms might protect areas from access by larger grazers, leaving remnants of biofilm as food for abalone recruits (Shepherd & Daume 1996, Day & Branch 2000) or as cues for larval settlement. This supposition is not supported by the observation that the lumpy coralline *Sporolithon durum* had no more biofilm than encrusting or warty forms (Shepherd & Daume 1996, Daume et al. 1999). However, the "lumps" on *Sporolithon durum* are several mm diameter, so would not restrict access for smaller grazers, and the sparse biofilm on this coralline probably results from its extensive epithallial sloughing (Shepherd & Daume 1996). In the present study, the effect of grazing refuges was clearly visible on some specimens of the fruticose *Mesophyllum printzianum*, where pockets of diatoms proliferated in the narrow gaps between protruberances or the sunken pore plates of conceptacles (Fig. 4E, F). Sloughing was also evident in some species (Fig. 5D) and contributed to the extreme variability in biofilm composition. This variability suggests that differences in biofilm characteristics

Figure 4. Selected features of the biofilm on *Mesophyllum pritzianum*. A. Light and dark areas on *Mesophyllum pritzianum* that are shown in photo B, to be patches with little surface polysaccharide and few bacteria (light areas) or copious polysaccharide and numerous bacteria. C. Bacteria and polysaccharide. D. SEM Method 2 of bacteria. E, F. Diatoms (*Tabularia* sp. and *Cocconeis pseudomarginata*) in grazing refugia.

Figure 5. SEM photos of coralline surfaces. A. *Lithophyllum carpophylli* showing high densities of coccoid bacteria in the cavities of CCA cells that have lost their exterior wall, although, B. shows that this was not always the case. C. *Phymatolithon repandum* showing a few bacteria among the fine debris that results from the disintegration of calcified cell walls. D. *Phymatolithon repandum* – the tissue at the left of the photo was newly exposed by epithelial sloughing and clear of diatoms, whereas older tissue had many diatom cells. E. Extensive grazing marks on *Phymatolithon repandum*. F. *Hydrolithon rupestris* with a moderately high density of bacteria. G. The growing edge of *Pncophyllum coronatum*. H. Abundant bacteria and a basal valve of *Cocconeis* sp. on *Pncophyllum coronatum*.

among CCA species are unlikely to explain consistent patterns in abalone settlement or postsettlement survival.

The CCA species used in the present study were from different locations, or different microhabitats within those locations (Table 2). Thus environmental effects such as growing conditions or grazing history could affect settlement preferences. Grazing could affect the inducing activity of CCA species by causing cell damage, allowing access to intracellular inducer molecules. CCA tissue can

be broken by the grazing of abalone (Shepherd & Cannon 1988, Shepherd & Daume 1996) and various other invertebrate grazers (Steneck & Watling 1982). In order for grazing damage to explain settlement preferences for certain CCA, the grazing would need to differentially affect the CCA species. In the present study grazing damage was evident on *Phymatolithon repandum* (Fig. 5E) and *Pncophyllum coronatum* but not on the favored *Hydrolithon rupestris*. CCA cell damage from grazing need not result in higher larval

Figure 6. Settlement response of larvae presented with a single species of coralline alga (No-choice Experiment 1). Settlement stages are Attached = larvae attached by their foot including those that have metamorphosed; Metamorphosed = larvae have shed their velum and may or may not have commenced postlarval shell growth; Shell growth = larvae that have shed the velum and initiated postlarval shell growth.

settlement. Daume et al. (1999) found that *Haliotis laevigata* larvae settling on the CCA *Sporolithon durum* lined up along the edges of cuts in the thallus, but the number of larvae that chose damaged plants was not significantly higher than that choosing undamaged plants. Johnson et al. (1991) found no difference in the number of *Acanthaster planci* larvae settling on damaged and undamaged *Lithothamnium pseudosorum*.

Figure 7. No-Choice Experiment 3: Settlement response of larvae presented with a single species of coralline alga (no choice). Settlement stages are defined as Attached = larvae attached by their foot including those that have metamorphosed; Metamorphosed = larvae have shed their velum and may or may not have commenced postlarval shell growth; Shell growth = larvae that have shed the velum and initiated postlarval shell growth.

Minimal Effect From Dissolved Inducers in Assays

In the present study, the corallines were broken into fragments for the experiments, so the specimens were not intact. Thus active chemicals may have leaked from the plants into the assay water. Water-soluble extracts of *Phymatolithon repandum* induce larval attachment, and sometimes metamorphosis, in *Haliotis iris* (Roberts & Nicholson 1997, R. Roberts unpubl. data). The concentration required to induce 50% larval attachment is generally between 100 and 200 μg dry extract per mL of water (R. Roberts unpubl. data). It is unlikely that this concentration would be produced by leakage from damaged edges in the settlement assays, but some effect from soluble inducers cannot be ruled out. Water soluble inducers would cause larvae to cease swimming and begin crawling within several minutes (R. Roberts unpubl. data). Crawling larvae may find access easiest for those corallines supported on flat plastic sheet (*Pneophyllum coronatum* and *Hydrolithon rupestris*), and this differential accessibility could confound results. In Choice Experiment 2, the CCA fragments were soaked in FSW for 4 days before assayed to reduce any effect from leaking cell contents. Settlement preferences were not appreciably altered (Fig. 1A, B). Experiment 3 tested the accessibility issue by pressing the coralline samples into clay so that the live surface of each specimen was flush with the surrounding substratum and all plants were equally accessible to crawling (or sinking) larvae. Larvae still displayed the same preference for *Pneophyllum coronatum* and *Hydrolithon rupestris* over the remaining species.

Timing of Observations in Settlement Choice Experiments

To detect preferential settlement, counts had to be made early enough to precede the movement of postlarvae off CCA, but late enough to let larvae respond to the CCA. Counts made after 1 day were informative despite the variation in speed of metamorphosis between larval batches. In all cases there was some movement of metamorphosed animals off CCA between 1 and 3 days after settlement (Fig. 8). *Haliotis iris* remain on the upper surfaces of CCA-coated boulders for a few months after settlement (McShane & Naylor 1995) so their movement off CCA in the present study would not be in search of shelter or darkness. It is likely to be caused by food depletion, as the experiments used high densities of larvae (Table 1) on small fragments of CCA (e.g., Fig. 2C). Newly metamorphosed postlarvae are capable of eating small, loosely attached particles including diatoms and bacteria (Seki & Kan-no 1981, Norman-Boudreau et al. 1986, Roberts et al. 1999a, b), and 6-wk old postlarvae can ingest the cuticle and epithelial cells of CCA (Garland et al. 1985). Copious fecal pellets (devoid of diatoms and CCA cells) are visible around CCA-coated pebbles within 2 days of settlement induction (R. Roberts, pers. obs.). This extracellular food source would probably be quickly depleted at high postlarval densities.

How Should Target Size be Measured?

Competent abalone larvae periodically cease swimming, sink to the bottom, pull themselves onto their foot. They may crawl some distance while testing the surface for the presence of settlement cues (Seki & Kan-no 1981). The larvae require surface contact to respond to intact corallines, rather than showing taxis toward the source of a water-borne cue (Morse et al. 1980). The appropriate "target size" for larvae sinking through the water column is the "floor area" covered by the CCA fragment, as measured here. For crawling larvae, the distance around the perimeter of the fragment

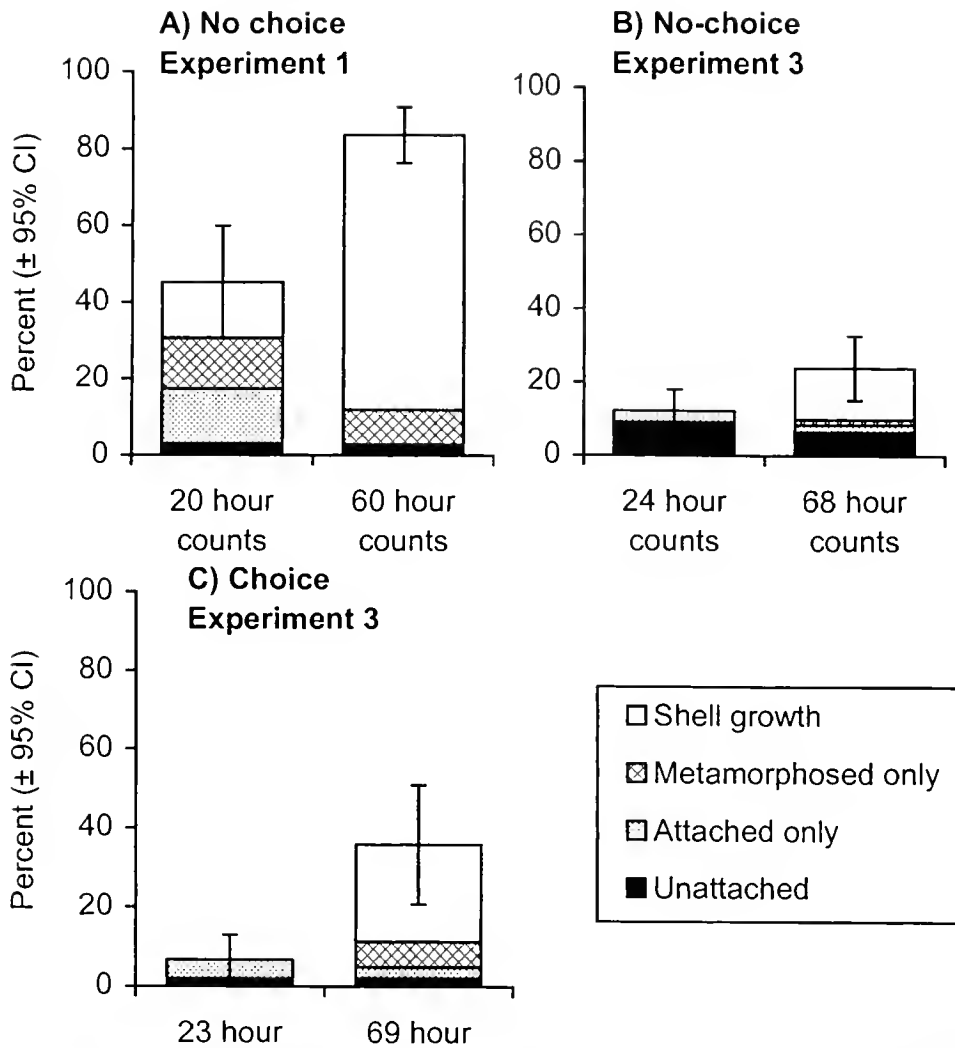

Figure 8. Number and developmental stage of abalone found "not on CCA" after ~1 day and ~3 days of bioassay. Settlement stages are defined as Unattached = larvae have not attached or metamorphosed; Attached only = larvae have attached but not metamorphosed; Metamorphosed only = larvae that have shed the velum but not grown any postlarval shell; Shell growth = larvae that have shed the velum and initiated postlarval shell growth. Confidence intervals apply to the totals for each column.

is most relevant, but the floor area measurement is a reasonable approximation for objects that are not long and thin.

CONCLUSION

Although the five species of CCA tested were all effective inducers of *Haliotis iris* larval attachment and metamorphosis, larvae did exhibit a preference for certain species when given a choice. This selection of certain substrata most likely results from different probabilities of acceptance or rejection following contact with a substratum. This study emphasizes the strong effect of selective settlement even among a suite of highly effective settlement substrata. From these laboratory results it is hypothesized that recruitment of *Haliotis iris* in the wild would vary among CCA species

or growth forms, and that this variation is at least partly determined at the time of larval settlement.

ACKNOWLEDGMENTS

The authors thank Sabine Daume and Bill Woelkerling for tuition and expertise on corallines identification, and for helpful discussions; Christine Handley for technical assistance; Mark Gould for guidance on scanning electron microscopy and Mike Barker and Philip Mladenov for review of drafts. ¹Ocean Research Institute, The University of Tokyo, Nakano, Tokyo 164-8639, Japan; ²Tohoku National Fisheries Research Institute, Shiogama, Miyagi 985-0001, Japan; ³Maizuru Fisheries Research Station, Field Science and Education Research Center, Kyoto University, Maizuru, Kyoto 625-0086, Japan

ABSTRACT The effect of grazing by a small herbivorous gastropod *Homalopoma amussitatum* on the density and species composition of benthic diatoms was examined in the laboratory. *H. amussitatum* is a dominant species on exposed crustose coralline algae (CCA) along the Sanriku coast in northeastern Japan, and it has been suggested that it competes for food with postlarval abalone. The minimum densities of the gastropod required to inhibit the growth of diatoms were estimated to be <10 g/m² at 20°C, between 10–20 g/m² at 15°C, and >20 g/m² at 7°C. In the absence of grazing pressure, *Nitzschia* sp. and *Psamodictyon pandurifolium*, which have a growth form classified as Type A (gliding prostrate type), initially formed flat communities. *Amphora* sp., *Cocconeis sublittoralis* (Type B: adhesive prostrate type) and *Tabularia investiens* (Type C: nonmotile upright type) subsequently increased in number. The two species of Type A were significantly affected by grazing pressure and did not increase even at a gastropod density of 10 g/m² at 15°C and 20°C. Types B and C diatoms were more tolerant of grazing by the gastropod than Type A species. However, the volumetric rate of ingestion of *Cocconeis scutellum* (Type B) by the gastropod was almost the same as for *Navicula britannica* (Type A) at the three experimental temperatures, when they were supplied to the gastropod independently. The digestion efficiencies of *C. scutellum* and *N. britannica* were 94.7% and 2.2%, respectively. The dietary value of *C. scutellum* for the gastropod *H. amussitatum* is thus considerably higher than that of *N. britannica*. In the natural CCA habitat, competitive grazing by *H. amussitatum* on the diatom *Cocconeis* spp., which is known as a major food for postlarval abalone, could significantly affect the survival and growth rates of postlarval abalone.

KEY WORDS: benthic diatom, grazing, gastropod, post-larval abalone, competition

INTRODUCTION

Benthic diatoms are the principle food for postlarval abalone (e.g., Kawamura 1996, Kawamura et al. 1998c). The abundance and species composition of benthic diatom communities on crustose coralline algae (CCA), where abalone larvae predominantly recruit (e.g., Saito 1981, Morse & Morse 1984), are suggested to significantly affect the survival and growth of metamorphosed abalone (Kawamura et al. 1998c, Takami et al. 1997, Takami et al. 2000). However, there is little information on the diatom communities on CCA surfaces in natural habitats. On CCA, there are many herbivores other than abalone (e.g., Asano et al. 1990, Kawamura et al. 1992), and their grazing controls the benthic diatom communities colonizing CCA (Kawamura 1994a, Kawamura 1994b). Herbivorous gastropods were determined to be the main grazers on benthic diatoms, controlling their abundance and species composition on CCA at several sites along the Sanriku coast in northeastern Japan (Kawamura et al. 1992, Kawamura 1994b, Takami 2002). When the densities of gastropods were high, diatom densities were low and grazer-tolerant species dominated regardless of other environmental factors (Kawamura et al. 1992, Kawamura 1994b). Three-dimensional communities developed only when the densities of gastropods were low (Kawamura et al. 1992, Kawamura 1994b). The effect of grazing by herbivorous gastropods on microalgal composition has been studied qualitatively (e.g., Nicotri 1977, Suzuki et al. 1987, Steinman et al. 1989) but not quantitatively.

A small herbivorous gastropod *Homalopoma amussitatum* Gould 1861 is a dominant species on CCA along the Sanriku coast in northeastern Japan (Kawamura et al. 1992, Kawamura 1994b,

Takami 2002) and has been suggested that it competes for food with postlarvae of the abalone *Haliotis discus hannai* Ino 1953 (Takami et al. 2001). Postlarval *H. discus hannai* reared with *H. amussitatum* showed significantly slower growth than postlarvae reared with 1-y-old *H. discus hannai* (Takami et al. 2001). There was no significant difference in the overall density of benthic diatoms between aquaria with *H. amussitatum* and with 1-y-old *H. discus hannai*, but the composition of diatom species differed among aquaria. The diatoms with a high dietary value for postlarval abalone, such as *Cocconeis* spp. (Kawamura et al. 1998c), had higher densities in aquaria with 1-y-old abalone than in aquaria with *H. amussitatum* (Takami et al. 2001).

In this study, the effect of grazing by *H. amussitatum* on the density, species composition and community structure of benthic diatoms was examined quantitatively in the laboratory. Benthic diatom communities are composed of species with various growth forms (Kawamura & Hirano 1992). Growth form influences tolerance of grazing (Kawamura & Hirano 1992, Kawamura 1994a, Kawamura 1994b) and affects ingestibility and digestion efficiency of diatoms for grazers, thus determining their nutritional value (Kawamura et al. 1995, 1998b, Roberts et al. 1999). Diatom species have been divided into 8 types (Types A to H) of growth form (see Materials and Methods). Feeding rates of the gastropod on 2 monoculture diatom strains with different growth forms (*Navicula britannica* Hustedt et Aleem 1951; Type A, *Cocconeis scutellum* Ehrenberg 1838; Type B) were measured. Diatoms with a Type A growth form are generally readily grazed, whereas those with Type B are less affected by grazing (Kawamura & Hirano 1992, Kawamura 1994a, Kawamura 1994b). However, Type A diatoms, which have low attachment strength, were easily ingested by postlarval abalone *H. discus hannai* (Kawamura et al. 1995) and *H. iris* Gmelin 1791 (Kawamura et al. 1998b) without cell rupture. The majority of ingested cells passed through the gut alive

*Corresponding author. E-mail: kawamura@ori.u-tokyo.ac.jp

and unharmed, resulting in low digestion efficiencies and thus low abalone growth rates (Kawamura et al. 1995, Kawamura et al. 1998b). The digestibility of diatom cells has only been examined for abalone. The digestion efficiency of two diatom strains for *H. amussitatum* was examined. We discuss the results of the present study in light of the competition for food between post-larval abalone and *H. amussitatum* previously reported by Takami et al. (2001).

MATERIALS AND METHODS

Effect of Grazing on Benthic Diatom Communities

Diatom communities colonizing glass slides were held in aquaria ($17 \times 19 \times 17.5 \text{ cm}^3$) under natural light conditions at Tohoku National Fisheries Research Institute, in Shiogama, Miyagi, Japan. Aquaria were supplied with sand-filtered and temperature-controlled seawater (1.1–1.2 L/min.) at 7°C, 15°C, and 20°C. Glass slides were set on the bottom of each aquarium. Adult *H. amussitatum* were kept at 4 biomasses (0, 10, 20, 40 g/m²). The gastropods were collected in the coastal waters off Eno-shima Island and were acclimated to the experimental seawater temperatures in advance. The shell height and wet weight of gastropods ranged between 5.0–11.0 mm ($7.5 \pm 0.1 \text{ mm}$; mean \pm standard error) and 0.1–0.6 g ($0.22 \pm 0.03 \text{ g}$), respectively. Two glass slides from duplicate aquaria were collected at 7–10-day intervals over 45 days. Density, species, composition, and growth form of diatoms colonizing the upper surface of the glass slides were examined under a light microscope. Diatom species were identified by a scanning electron microscope after acid cleaning (Takano & Nagumo 1987).

Growth forms of benthic diatoms are classified into 8 types (Types A to H) based on their mode of attachment, whether solitary or colonial forms, and by their motility and adhesive strengths (Kawamura & Hirano 1992, modified by Kawamura 1994a). The major diatom species colonizing glass slides in the present experiment were divided into the 4 types of growth form (Types A, B, C, and E). Type A (gliding prostrate type): solitary cells with a prostrate form, swift gliding movements, and very low adhesive strength. Type B (adhesive prostrate type): solitary cells with a prostrate form, slow movement, and high adhesive strength. Type C (nonmotile upright type): nonmotile solitary cells or simple, fan-shaped colonies standing upright with a relatively weak adhesion to the substratum. Type E (mucous thread solitary type): solitary cells or short, belt-shaped colonies attached strongly to the substratum with a mucous thread.

The differences in diatom density among experimental treatments were tested using Tukey-Kramer multiple comparison test.

Feeding Rates on Two Diatom Species

Feeding rates of *H. amussitatum* were measured individually at 7°C, 15°C, 20°C on 2 monoculture diatom strains (*Navicula britannica*: Type A, *Cocconeis scutellum*: Type B) by counting the diatom cell number in the feces. Cell volume of the diatoms, *N. britannica* and *C. scutellum* were $2343.4 \mu\text{m}^3$ ($55.4 \times 9.0 \times 4.7 \mu\text{m}$) and $730.8 \mu\text{m}^3$ ($22.0 \times 15.1 \times 2.2 \mu\text{m}$), respectively. Gastropods ($6.4 \pm 0.2 \text{ mm}$ in shell height, $0.16 \pm 0.01 \text{ g}$ in wet weight) were reared individually, in triplicate at each temperature, in deep petri dishes (9 cm in diameter, 2 cm in depth) with diatoms growing on the bottom. All fecal pellets released by the gastropods were collected at 12- or 24-h intervals. Diatom cell numbers in the feces

were calculated from the number of valves counted with a light microscope after acid cleaning (Takano & Nagumo 1987). Gut passage time of diatoms was measured by changing diatom species, and measuring the time before new diatoms appeared in the feces.

Recently released fecal material of *H. amussitatum* ($n = 3$ for each diatom strain) reared at 20°C was observed with an inverted microscope, and the proportions of intact versus ruptured diatom cells in feces were counted. A parallel count was made of live versus ruptured cells in the diatom culture from which the fecal material was grazed. Digestion efficiency (%) was calculated as: $(1 - L/L_0) \times 100$, where L_0 is the proportion of live cells in the source culture, and L is the proportion of live cells in the fecal pellet.

RESULTS

Effects of Grazing on Benthic Diatom Communities

At 20°C, *Nitzschia* sp. (Type A) initially formed flat communities in the absence of grazing by the gastropod and significantly increased at Day 15 (Fig. 1, $P < 0.05$). After Day 25 *Amphora* sp. (Type B) significantly increased ($P < 0.05$) and dominated. After Day 35 *Tabularia investiens* (Wm. Smith) Williams and Round 1986 (Type C) had significantly increased ($P < 0.05$) in number and was the second-most dominant species. *Achnanthes brevipes* var. *intermedia* (Kützing) Cleve 1895 (Type E) also slightly increased in number by Day 35 but was not abundant. *Nitzschia* sp. and *Amphora* sp. almost disappeared in aquaria with gastropods ($10\text{--}40 \text{ g/m}^2$) at 20°C. *Cocconeis sublittoralis* Hendey 1951 (Type B) also decreased in number under grazing pressure. The density of *Cocconeis scutellum* was higher in aquaria with gastropods ($10\text{--}40 \text{ g/m}^2$) than without gastropods (0 g/m^2). At Day 45 *C. scutellum* was dominant in aquaria with gastropods at 20 and 40 g/m² ($P < 0.05$). Remarkably, the density of *T. investiens* increased after Day 35 in aquaria with gastropods at 10 g/m² ($P < 0.05$) to be comparable in aquaria without gastropods. This diatom de-

Figure 1. Changes in density of diatoms classified into growth forms (A, B, C, E) with four densities of *Homalopoma amussitatum* (0, 10, 20, 40 g/m²) at 20°C. Bars indicate standard errors of the mean ($n = 4$).

increased in number in aquaria with gastropods at 20 and 40 g/m² ($P < 0.05$), but was second-most dominant after *C. scutellum* at Day 45 ($P < 0.05$) (Fig. 1).

At 15°C, successions of diatom communities in aquaria without grazing (0 g/m²) were similar to those at 20°C, although growth rates of diatoms were lower (Fig. 2). *Nitzschia* sp. was most affected by grazing, and did not increase in aquaria with gastropods at 20 and 40 g/m² ($P < 0.05$). The density of *Amphora* sp. was significantly lower in aquaria with gastropods than without ($P < 0.05$), but relatively high in aquaria with gastropods at 10 g/m² after Day 35 ($P < 0.05$). *Psammодиетон panduriforme* (Gregory) Mann 1990 (Type A) and *C. sublittoralis* were generally less abundant in aquaria with gastropods, but their density in aquaria with 10 g/m² of gastropods was significantly higher than those in aquaria without gastropods after Day 35 ($P < 0.05$). *T. investiens* increased to a high density in aquaria with gastropods at 10 g/m² after Day 35 ($P < 0.05$), whereas it was not abundant in aquaria without gastropods (Fig. 2) ($P < 0.05$).

Densities of the 3 dominant species (*Nitzschia* sp., *Amphora* sp., and *C. sublittoralis*) at 7°C were all lower in aquaria with gastropods than those in aquaria without gastropods (Fig. 3). However, the densities of diatoms were less affected by grazing at 7°C than at higher temperatures, and the diatoms gradually increased in number in aquaria with gastropods at 10 and 20 g/m² ($P < 0.05$). In aquaria with gastropods at 40 g/m², only the density of *C. sublittoralis* increased slightly (Fig. 3), but there was no significant difference in the density of *C. sublittoralis* during the experimental period ($P > 0.05$).

Feeding Rates on Two Diatom Species

Gut passage time of diatoms was longer at lower temperatures but within 24 h even at 7°C. Because the gastropods were feeding and producing fecal material almost continuously, the number of

Figure 2. Changes in density of diatoms classified into growth forms (A, B, C) with 4 densities of *Homalopoma amussitatum* (0, 10, 20, 40 g/m²) at 15°C. Bars indicate standard errors of the mean ($n = 4$).

Figure 3. Changes in density of diatoms classified into growth forms (A, B) with four densities of *Homalopoma amussitatum* (0, 10, 20, 40 g/m²) at 7°C. Bars indicate standard errors of the mean ($n = 4$).

diatom cells in feces excreted in 24 h was considered to be equal to the amount of material ingested daily by an individual gastropod. The amount of fecal material gradually increased during the first 3 days and was almost constant after Day 3. The ingestion rate for the three seawater temperatures, calculated from the number of diatom cells excreted between Day 3 and Day 5, is shown in Table 1. The volume of each diatom strain ingested per g gastropod per day was almost the same, although the daily number of *N. britannica* cells ingested was less than *C. scutellum*. The digestion efficiency of *C. scutellum* at 20°C was 94.7%, whereas that of *N. britannica* was 2.2% (Table 1).

DISCUSSION

The succession of diatom communities, from Type A species (*Nitzschia* sp. and *P. panduriforme*) to Type B (*Amphora* sp. and *C. sublittoralis*) and Type C (*T. investiens*), dramatically changed with grazing by *H. amussitatum*. *Nitzschia* sp. and *P. panduriforme* of Type A growth form were affected more by grazing than diatoms of Types B and C (Figs. 1–3). It has been reported that

TABLE 1.

The ingestion rate and digestion efficiency of two diatom strains grazed by *Homalopoma amussitatum* at three temperatures.

Temperature (°C)	Diet	Ingestion rate		Digestion Efficiency (%)
		(Cells/g · Day, Mean ± SE)	(µm ³ /g · Day, Mean)	
7	<i>C. scutellum</i>	(1.5 ± 0.3) × 10 ⁹	1.1 × 10 ⁹	
	<i>N. britannica</i>	(3.0 ± 1.2) × 10 ⁵	7.0 × 10 ⁸	
15	<i>C. scutellum</i>	(6.4 ± 0.9) × 10 ⁹	4.7 × 10 ⁹	
	<i>N. britannica</i>	(1.5 ± 0.2) × 10 ⁹	3.5 × 10 ⁹	
20	<i>C. scutellum</i>	(8.3 ± 1.9) × 10 ⁹	6.1 × 10 ⁹	94.7
	<i>N. britannica</i>	(2.6 ± 0.3) × 10 ⁹	6.1 × 10 ⁹	2.2

Type A species are susceptible to being ingested by gastropods such as abalone (Ioriya & Suzuki 1987, Suzuki et al. 1987) and amphipods (Kawamura & Hirano 1992). The results of the present experiment showed that the two species of Type A growth form were most easily grazed by *H. amussitatum*.

At 15°C, the density of *T. investiens* in aquaria with gastropods at 10 g/m² was significantly higher than those in aquaria without gastropods after Day 35 (Fig. 2). At 20°C, the density of *T. investiens* in aquaria with gastropods at 10 g/m² also increased to be comparable in aquaria without gastropods (Fig. 1). The growth form of this species is easily grazed, and appeared to be abundant when grazing pressure was low in Tomarihama Bay in Miyagi (Kawamura et al. 1992). On the contrary, the density of this species was high under relatively high grazing pressure in Yoshihama Bay in Iwate (Kawamura 1994b). The dominant gastropod species were *Omphalius rusticus* Gmelin 1791 in Tomarihama Bay and *H. amussitatum* in Yoshihama Bay. Probably because *H. amussitatum* does not prefer to graze *T. investiens* (for unknown reasons other than growth form), this diatom appeared to increase when other diatoms were reduced by grazing. However, densities of this diatom were low in aquaria with gastropods at 20 and 40 g/m² (Figs. 1 and 2). It is suggested that *H. amussitatum* grazes *T. investiens* when food sources are limited.

Because the relative abundance of diatom species with a Type B growth form was high when the density of gastropods was high in Tomarihama Bay (Kawamura et al. 1992) and Yoshihama Bay (Kawamura 1994b), this type of diatom seemed to be relatively tolerant to grazing. The results of the present experiment showed that densities of *Amphora* sp. and *C. sublittoralis* (Type B) markedly decreased under the influence of grazing by *H. amussitatum*. On the other hand, *C. scutellum* of Type B appeared in relatively high density when grazed at 20°C (Fig. 1). A similar phenomenon was observed on settlement plates of abalone larvae in hatcheries (Ioriya & Suzuki 1987, Suzuki et al. 1987). This species may be able to increase growth under relatively high grazing pressure and/or when other diatoms are reduced by grazing, like *T. investiens*. However, the daily volume of *C. scutellum* cells ingested by the gastropod was almost the same as that of *N. britannica* cells when each diatom strain was supplied independently (Table 1). The digestion efficiency of *C. scutellum* was high, whereas most of *N. britannica* cells ingested by the gastropods passed through the gut alive and unbroken (Table 1). Although growth and nutritional condition of the gastropods were not examined in this study, *C. scutellum* seems to be a much more efficient diet than *N. britannica* for the growth of *H. amussitatum*, as previously found for abalone (Kawamura et al. 1995, Takami et al. 1996, Roberts et al. 1999). Many gastropods, such as abalone and *H. amussitatum*, probably graze all the microalgae growing on substrata regardless of their dietary value, with exceptions like *T. investiens*. Diatoms with Type B growth form are relatively hard to graze because they require considerable force to be removed, but if dislodged their cells are usually broken and release cell contents (Kawamura et al. 1995, Kawamura et al. 1998b, Roberts et al. 1999). For gastropods that can detach Type B diatom cells from substrata, these diatoms are efficient food sources because the diatom cell contents can be utilized.

Post-larval abalone can initially grow on biofilm materials including extracellular substances of diatoms, but larger postlarvae (>0.6–0.8 mm SL) need to use diatom cell contents for adequate growth (Kawamura et al. 1998c, Roberts et al. 1999). By approxi-

mately 0.8 mm SL postlarval *H. discus hannai* can detach *Cocconeis* cells efficiently, probably due to morphologic changes in the radula (Kawamura et al. 2001). Grazer-resistant algae such as Type B diatoms tend to dominate on CCA surfaces due to the high grazing intensity by gastropods. Dense patches of *Cocconeis* spp. were observed on CCA where postlarval and juvenile abalone were present (Takami 2002). Postlarval abalone that settled on CCA seemed to feed and grow mainly on *Cocconeis*. However, juvenile abalone of larger than 5–10 mm SL do not graze *Cocconeis* species if more favorable foods are available (Kawamura et al. 1998c), probably because the energetic value of *Cocconeis* ingestion becomes insufficient to support rapid growth due to their low-volume cells, prostrate growth form (Takami et al. 1996), and single layered colonies (Kawamura et al. 1998a). *H. discus hannai* larger than 1.8 mm SL use juveniles of the macroalga *Laminaria japonica* Areschoug 1851 efficiently (Takami et al. 2003). Juvenile and adult abalone graze 3-dimensional colonies of diatoms and loosely attached diatom cells simultaneously with their favored juvenile macroalgae, leaving behind prostrate diatoms with high attachment strength. Therefore *Cocconeis* spp. are often dominant on abalone larval settlement plates, which are pregrazed by conspecific juvenile abalone in hatcheries (Ioriya & Suzuki 1987, Suzuki et al. 1987, Seki 1997). It is considered that juvenile and adult abalone do not compete for food with postlarval abalone. On the other hand, the results of this study show that adult *H. amussitatum* is potentially a strong competitor for *Cocconeis* with postlarval abalone on CCA, as also suggested by Takami et al. (2001).

From the results of this study, the minimum densities of the gastropod *H. amussitatum* required to inhibit the growth of diatoms (except *T. investiens*) were estimated to be below 10 g/m² at 20°C, between 10 and 20 g/m² at 15°C, and above 20 g/m² at 7°C. On rocks covered by CCA in Tomarihama Bay, the density of herbivorous gastropods dominated by *H. amussitatum* was between 9.0 and 28.6 g/m² in 1989, and over 20 g/m² during the spawning season of the abalone *H. discus hannai* between August and October (Kawamura et al. 1992). Because the seawater temperature was over 15°C, most benthic diatoms that colonized CCA surfaces were probably eaten by gastropods. Postlarval abalone that settled on the CCA surfaces were unlikely to get sufficient food. During the study period in Tomarihama Bay, we did not collect any juvenile wild abalone from CCA rocks, although adult abalone and released juveniles lived nearby.

Sasaki and Shepherd (2001) reported that significant numbers of postlarval *H. discus hannai* of 5–7 days old, collected from boulders covered by CCA in Samenoura Bay, Miyagi in 1996 and 1997, showed an atrophied condition due to starvation. They hypothesized that the abundance of postlarvae of an herbivorous gastropod *Tegla* in the same habitat might cause food limitation and thus low survival of postlarval abalone. The results of the present study and Takami et al. (2001) indicated that a high density of gastropods such as *H. amussitatum* may affect abalone recruitment through competition for food.

GROWTH AND SURVIVAL OF JUVENILE RED ABALONE (*HALIOTIS RUFESCENS*) FED WITH MACROALGAE ENRICHED WITH A BENTHIC DIATOM FILM

JORGE ARTURO SIMENTAL, MARÍA DEL PILAR SÁNCHEZ-SAAVEDRA,* AND NORBERTO FLORES-ACEVEDO

Laboratorio de Biología y Cultivo de Microalgas, Departamento de Acuicultura, Centro de Investigación Científica y de Educación Superior de Ensenada, Apdo. Postal 2732, C.P. 22860 Ensenada, Baja California, México.

ABSTRACT The objective of this work was to evaluate the growth rate of 150-day-old juvenile abalone *Haliotis rufescens* fed with blades of the seaweed *Macrocystis pyrifera* epiphyted with a film of the benthic diatom *Navicula incerta*. Five treatments were used as food for juvenile abalone: (1) blades of *M. pyrifera* washed for 10 min with fresh water to remove natural epiphytes; (2) blades of *M. pyrifera* without natural epiphytes and colonized with *N. incerta* at an initial density of approximately 500 cells mm⁻²; (3) blades of *M. pyrifera* with natural epiphytes; (4) blades of *M. pyrifera* with natural epiphytes and colonized with *N. incerta*; and (5) batch cultures of *N. incerta* without blades. All treatments were kept on 18-L plastic buckets with 10 L of "f/2" medium at 16°C and 100 μEm⁻²s⁻¹ of continuous light. All treatments were kept under culture conditions for 2 days. Plastic buckets of 18 L filled with 10 L of filtered seawater at 16°C was used for the bioassay with the red abalone. The five feeding treatments were provided *ad libitum* to juvenile abalone and were removed after 4 days. The water exchange rate in the buckets was ~300% per day. Every 15 days, and for a period of 90 days, weight and growth (as shell length and width) were measured. At the end of the experiment mortality was determined. The results showed that the highest growth rates and weight were observed in treatments 2, 4, and 5 whereas the lowest growth rates and weight were observed in treatments 1 and 3. The highest average survival was recorded in treatment 5 (52.17%), whereas the lowest was observed in treatment 2 (34.20%). This study showed that the enrichment of seaweed blades improves growth and survival in abalone and thus has potential to be used in abalone farms to enhance productivity.

KEY WORDS: benthic diatoms, epiphytes, seaweed, *Haliotis rufescens*, *Navicula incerta*, *Macrocystis pyrifera*

INTRODUCTION

Commercial abalone culture in México and California has traditionally been based on the supply of benthic diatoms as food for abalone postlarvae. When juvenile abalone reach a size of approximately 10 mm, the type of nourishment changes from benthic diatoms to seaweed. The main seaweed species used as food for juvenile and adult abalone are *Macrocystis pyrifera*, *Nereocystis luetkeana*, and *Egria menziesii*, these and other brown seaweeds of the North Pacific coasts are abundant and easy to harvest from coastal waters (Hahn 1989, Buchal et al. 1998, McBride 1998).

The biochemical composition of seaweed varies among species and is related to the geographical zone, season, currents and wave exposure, nutrient availability, depth, temperature, and life stage of the algae (Cruz-Suárez et al. 2000). This variability in nutritional value produces heterogeneous growth rates and, in some cases, low growth in abalone (Bautista-Teruel & Millamena 1999).

The biochemical composition of the seaweed *Macrocystis pyrifera* is poor, ranging from 5% to 12% proteins, 0.5% to 1% lipids, and 46% to 50% carbohydrates (Cruz-Suárez et al. 2000). Benthic diatoms have a much better biochemical composition, 22% to 36% proteins, 13% to 58% lipids, and 5% to 23% carbohydrates (Renaud et al. 1999, Simental-Trinidad et al. 2001).

When the food for juvenile abalone is changed from benthic diatoms to seaweed it is believed to reduce growth and survival, and may be a factor involved in high mortalities of the organisms under culture conditions. The biochemical composition of seaweed can be enhanced by the performance of a selective colonization over the surface of the blade with benthic diatoms. The aim of this work is to improve the growth rate and survival of juvenile red abalone (*Haliotis rufescens*) by enhancing the biochemical com-

position of its food (*Macrocystis pyrifera*) with a selective epiphytation of the seaweed blades with the benthic diatom *Navicula incerta*.

MATERIALS AND METHODS

Blades of the seaweed *Macrocystis pyrifera* (excluding pneumatocysts) and cultures of the benthic diatom *Navicula incerta* were used in this work. The seaweed *M. pyrifera* was harvested every 4 days from a mantle located at Punta Morro (31°51'30"North, 116°38'38"West), on the coastal waters of Bahía Todos Santos, Baja California (BC), México. Every 4 days, from August to November 2002, seaweed was harvested at a depth of 2 m from the apical blades. The benthic diatom *N. incerta* was isolated from the same location by the staff of Universidad Autónoma de Baja California, and was also obtained by donation from the abalone farm "Abulones Cultivados" Ejido Eréndira, BC, México.

This study used 150-day-old juveniles of red abalone *Haliotis rufescens*, which were obtained from the earlier mentioned abalone farm. The abalone were selected to provide a group with an average shell length of 3.67 mm ± 0.32 and weight of 0.0055 g ± 0.0015. Organisms were acclimated to the experimental conditions for a period of 1 wk and fed *M. pyrifera ad libitum*.

Five treatments were used to provide food to juvenile abalone: (1) blades of *M. pyrifera* without natural epiphytes; (2) blades of *M. pyrifera* without natural epiphytes and colonized with *N. incerta*; (3) blades of *M. pyrifera* with natural epiphytes; (4) blades of *M. pyrifera* with natural epiphytes and colonized with *N. incerta*; and (5) batch cultures of *N. incerta* without blades.

All treatments were performed by triplicate and kept under controlled light irradiance (100 μEm⁻²s⁻¹). The temperature for the experimental containers was maintained at 16°C by using an electronic controller.

*Corresponding author. E-mail: psanchez@cicese.mx

The seawater used for all experiments was passed through sand and cartridge filters of 10 μm and 5 μm , and finally irradiated with ultraviolet light. Cultures of *N. incerta* were prepared for inoculum in "f/2" medium (Guillard & Ryther 1962) in progressive volumes of 10 mL, 150 mL, 900 mL, and 10 L. The strain was acclimated to the culture conditions of temperature and continuous light previously described. For the production of the 10-L inoculum used in the bioassay with juvenile abalone, circular 18-L white plastic containers (30 \times 35 cm) with a lexon acrylic lid at the top were used (Simental-Trinidad et al. 2001). An initial density of 150 organisms per container was used in the bioassay. Seawater was exchanged at approximately 300% per day.

For treatment 1, blades of *M. pyrifera* were washed with freshwater for 10 min to remove all the natural epiphytes. After the bath, sets of two blades were placed in the plastic container with 10 L of "f/2" medium. For treatment 2, blades of seaweed were treated similarly to those in treatment 1, and were inoculated with a 4-day-old culture of *N. incerta* at an initial density of 50,000 cells ml^{-1} (obtaining approximately 500 cells mm^{-2} on the blade surface). For treatment 3, the seaweed blades were placed into the containers without any previous washing or inoculation. For treatment 4, the blades of *M. pyrifera* without previous washing were inoculated with *N. incerta*, similarly to the process described in treatment 2. Treatment 5 was a monospecific culture of *N. incerta* with the same cell density as the one used in treatments 2 and 4.

Two days after the setting of the 5 treatments, all were given as food to the abalone *ad libitum* and left for 4 days, after that time, excess food was removed and new treatments were added to the containers.

Every 15 days, and for a period of 90 days, weight and shell length were obtained by randomly sampling 15 organisms. Weight was measured with an electronic scale and shell length was measured by using a calibrated compound microscope. At the end of the experiment, survival of juvenile abalone was determined. Daily growth rates, in terms of weight (DGW) and shell length (DGSL), were evaluated as described by Capinpin & Corre (1996). Growth rate was calculated as follows:

$$\text{DGW } (\mu\text{g per day}) = \text{Gw}/n;$$

and

$$\text{DGSL } (\mu\text{m per day}) = \text{Gsl}/n;$$

where Gw is the increase in weight (μg), Gsl is the increase in shell length (μm) and n are the days of rearing.

To determine if there were significant differences in weight through time as a result of different treatments, a covariance statistical analysis was used. The same analysis was performed to determine differences in shell length, and shell width. To determine if there were significant differences in growth rates, a 1-way Anova was used. When differences were detected, a Tukey *a posteriori* test was performed. All the differences were evaluated at $\alpha = 0.05$. For all statistical analysis, the software Statistica 5.0 for Windows was used.

RESULTS

Significant differences in weight among treatments were detected ($F = 75.83$, $P < 0.00$) (Fig. 1). The highest weights were detected in treatments 2 (0.100 g \pm 0.005 SE) and 5 (0.080 g \pm 0.004). The lowest abalone weights were obtained on treatments 1 (0.046 g \pm 0.003 SE) and 3 (0.039 g \pm 0.001 SE).

Figure 1. Mean weight of 150-day-old red abalone *Haliotis rufescens* fed with different seaweed diets. Treatments were: (1) *Macrocystis pyrifera* without natural epiphytes; (2) *M. pyrifera* without natural epiphytes and with a layer of *Navicula incerta*; (3) *M. pyrifera* with natural epiphytes; (4) *M. pyrifera* with natural epiphytes and with a layer of *N. incerta*; and (5) Culture of *N. incerta* without blades. Vertical bars indicate standard error.

Shell length showed significant differences ($F = 132.03$, $P < 0.00$) (Fig. 2). The highest shell lengths were detected on treatments 2 (9.06 mm \pm 0.09 SE) and 5 (8.81 mm \pm 0.14 SE). The lowest shell lengths were detected on treatments 1 (6.76 mm \pm 0.09 SE) and 3 (8.20 mm \pm 0.14 SE).

Significant differences were obtained for shell width ($F = 46.06$, $P < 0.00$) (Fig. 3). A maximum value of shell width was recorded on treatment 2 (6.17 mm \pm 0.010 SE). The lowest values were detected on treatments 1 (4.57 mm \pm 0.07 SE) and 5 (5.66 mm \pm 0.08 SE).

The average daily growth rate for the 5 treatments in terms of weight and shell length of abalone for 0–30 days, 30–60 days, and 60–90 days are shown in Table 1. DGW showed significant differences ($F = 23.4$, $P < 0.00$) on days 30–60 and 60–90. Abalone fed on treatments 2, 4, and 5 produced the highest growth rates in terms of weight. Regarding growth rate expressed as DGSL, a decrease was observed from day 30 until the end of the experiment. There were significant differences only during the 30–60 day period, when abalone were fed on treatments 2, 4, and 5 and where the highest growth rates in terms of shell length were recorded.

Figure 2. Mean shell length of 150-day-old red abalone *Haliotis rufescens* fed with different seaweed diets. Treatments were: (1) *Macrocystis pyrifera* without natural epiphytes; (2) *M. pyrifera* without natural epiphytes and with a layer of *Navicula incerta*; (3) *M. pyrifera* with natural epiphytes; (4) *M. pyrifera* with natural epiphytes and with a layer of *N. incerta*; and (5) Culture of *N. incerta* without blades. Vertical bars indicate standard error.

Figure 3. Mean shell width of 150-day-old red abalone *Haliotis rufescens* fed with different seaweed diets. Treatments were: (1) *Macrocystis pyrifera* without natural epiphytes; (2) *M. pyrifera* without natural epiphytes and with a layer of *Navicula incerta*; (3) *M. pyrifera* with natural epiphytes; (4) *M. pyrifera* with natural epiphytes and with a layer of *N. incerta*; and (5) Culture of *N. incerta* without blades. Vertical bars indicate standard error.

Minimum and maximum survival is presented in Table 2. There were significant differences between repetitions, with a minimum survival value recorded on treatment 2 (9.56%) and a maximum survival value on treatment 4 (82.60%).

DISCUSSION

In natural populations, abalone are nonselective feeders (Leighton & Boolootian 1963). In Mexican farms, where commercial abalone production is performed, food supply is based on seaweed instead of formulated diets. The seaweed is used mainly because of its availability, easy harvesting methods, and low cost. The main species used are *Macrocystis pyrifera* and *Gracilaria* spp. (Carral-Miranda pers. com. 2003). Juvenile begin to eat macroalgae at about 10 mm in length and will eat from 10% to 30% of their whole-body wet weight in algae each day. The high feeding rate of macroalgae is due to the high water content and relative low protein content of fresh macroalgae (Hahn 1989).

Usually, the protein content of benthic diatoms, such as *Navicula* sp. under culture conditions, varies according to the age and culture conditions from 20% to 30%; whereas carbohydrate content ranges from 10% to 15%, and lipid content ranges between 15% to 20% (Flores-Vergara 1998, Correa-Reyes et al. 2001, Car-

bajal-Miranda 2002, Simental-Trinidad et al. 2001, Simental & Sanchez-Saavedra 2003).

In Mexican abalone farms, the change in nourishment, from microalgae to seaweed, is initiated when juvenile abalone are 3 mo old (Vázquez-Moreno pers. com. 2002) or when they are close to 10 mm in length. The daily seaweed portion that juvenile abalone receive ranges from 10% to 30% of their whole-body wet weight (Hahn 1989). According to Kawamura et al. (2001), the structure of the radula and digestive abilities for the use of seaweed as food is ready at 2–4 mm shell length in *H. discus hannai*, thus, the juvenile *H. rufescens* used in this experiment (3.67 ± 0.32 mm) were fully able to feed on seaweed.

In an experiment performed with deep-sea water and a continuous and simultaneous culture of the benthic diatom *Nitzschia* sp., used as food for 7-mo-old juvenile abalone *Haliotis sieboldi* ($12.4 \text{ mm} \pm 0.2 \text{ Sd.}$), daily growth rate of the organisms was 50 to $110 \mu\text{m day}^{-1}$. Such results show that continuous cultivation of *Navicula* sp. with deep seawater promotes growth of juvenile abalone, without the need for providing supplementary seaweed or artificial diets (Fukami et al. 1997). The best growth rate in length and weight of *H. rufescens* was obtained from treatments with selective epiphytation or enriched with the benthic diatom *Navicula incerta*. Juvenile abalone retains the ability to digest diatoms after developing the ability to digest macroalgae. A combined diet of benthic diatoms and macroalgae provides greater nourishment and faster growth rate.

A common practice on abalone farms is the washing of the seaweed blades to avoid the introduction of other algae, microorganisms, and bacteria. However, research has shown that the epiphytes can contribute to an increase in the chemical composition of seaweed (Simental-Trinidad 2003). When abalone were fed with blades of *Laminaria religiosa* with bryozoa (*Membranipora membranacea*) on the surface, they grew faster than those fed with the same species without bryozoa. These are evidences that bryozoa probably supply complementary nourishment to the abalone (Uki 1981). Research suggests that abalone also can use bacteria, yeast, and other micro-organisms associated with diatoms as food (McBride & Conte 2001).

Benthic diatoms are the main diet for small abalone (Voitolina 1985, 1994, Daume et al. 1997, Daume et al. 1999, 2000, Kawamura 1996, Kawamura et al. 1998a, Kawamura et al. 1998b; Roberts 2000; Searcy-Bernal et al. 2000). Some diatoms in feces were observed to have cytoplasm and nuclear material and were there-

* Treatments were: (1) *Macrocystis pyrifera* without natural epiphytes; (2) *M. pyrifera* without natural epiphytes and with a layer of *Navicula incerta*; (3) *M. pyrifera* with natural epiphytes; (4) *M. pyrifera* with natural epiphytes and with a layer of *N. incerta*; (5) Culture of *N. incerta* without blades. The standard error is included in parenthesis.

The different letters on the side of the quantities indicate significant differences (1-way Anova and Tukey *a posteriori* test, $\alpha = 0.05$): a < b.

TABLE 2.

Average survival and minimum and maximum values due to replicates (expressed in percentages) of juvenile red abalone *Haliotis rufescens*, after twelve weeks of feeding with different treatments* using the seaweed *Macrocystis pyrifera* and the benthic diatom *Navicula incerta*.

Treatment*	Survival		
	Average (%)	Maximum (%)	Minimum (%)
1	48.40	57.39	38.26
2	34.20	67.82	9.56
3	46.95	55.65	40.00
4	52.17	82.60	30.43
5	50.86	53.04	48.69

* Treatments were: (1) *M. pyrifera* without natural epiphytes; (2) *M. pyrifera* without natural epiphytes and with a layer of *N. incerta*; (3) *M. pyrifera* with natural epiphytes; (4) *M. pyrifera* with natural epiphytes and with a layer of *N. incerta*; (5) Culture of *N. incerta* without blades.

fore, assumed not to have been completely digested. In the gut content of *Haliotis asinina* collected from the natural environment, it was found that the main nourishment appears to be composed of benthic diatoms. Dominant genera in gut content were *Nitzschia*, *Ampelopsis*, *Navicula*, and *Cocconeis*, which were the predominant floral elements in the local environment (Sawatpeera et al. 1998). Relatively few diatom strains are ruptured when eaten by abalone postlarvae. Postlarvae <1 mm in shell length can grow using extracellular foods such as mucus from adult abalone. Postlarvae >1mm require the cell content of diatoms for rapid growth. The natural succession of diatom communities can be controlled, to some extent, by light and grazing pressure, thus, favoring useful diatoms (Roberts et al. 2000).

The nutritional value of monospecific cultures of eight benthic diatom species was determined for abalone postlarvae of *Haliotis rufescens*. The best growth rate, measured as shell length, was obtained when organisms were fed with *Amphiprora paludosa* var. *hyalina*, *Nitzschia thermalis* var. *minor*, and *Navicula incerta* (Correa-Reyes et al. 2001, Correa-Reyes 2002).

The growth rate obtained in this work varied from 9.15–63.32 $\mu\text{m day}^{-1}$. However, Kawamura et al. (1995) determined growth rates from 13.6–50.1 $\mu\text{m day}^{-1}$ in *H. discus hannai* fed with several benthic diatoms. Meanwhile, Neori et al. (2000) reported

growth rate values of 66.6 $\mu\text{m day}^{-1}$ in *H. discus hannai* fed with *Ulva lactuca* or *Gracilaria conferta*. In this experiment we obtained better growth rates when abalone were fed with blades of seaweed containing benthic diatoms. Another important consideration is that both species (*M. pyrifera* and *N. incerta*) are commonly used on abalone farms in México.

The use of seaweed as a food source on abalone farms has some other advantages due to the fact that they can also act as biologic filters and can be used as a coculture of abalone and seaweed (Evans & Langdon 2000). Thus, establishing the possibility for the use of systems with low water exchange or closed systems for the culture of abalone without the problem of losing stability of formulated diets, which in some cases lose as much as 24% of dry matter in their pellets (Guzmán & Viana 1998). Consequently, decreasing problems of waste removal and aeration, which are the main limiting factors, considered by many farmers, when using artificial diets (Fleming et al. 1996). Eutrophication by nitrogen can reduce the diversity of communities, and produce low water quality (Hillebrand & Sommer 2000). With seaweeds such as *Gracilaria* used as biofilters, 90% of the nitrogen present in the water can be removed (Ryther et al. 1982).

CONCLUSION

A significant increase in weight and shell length for juvenile abalone was determined over time when the organisms were fed with the algae *Macrocystis pyrifera*, selective epiphytes with cultures of the benthic diatom *Navicula incerta*, and with the monocultures of *N. incerta*. Growth rate and survival of juvenile abalone (*Haliotis rufescens*) can be increased by using the seaweed *Macrocystis pyrifera* and selective epiphytes with cultures of the benthic diatom *Navicula incerta* as feed.

ABSTRACT Abalone (*Haliotis* spp.) postlarvae are cultured in systems that provide natural or artificial light to promote the growth of benthic diatoms that are grazed by postlarvae. Larger abalones (>2 cm) grow better in dark conditions and the possibility that this is true for postlarvae is explored in this contribution. Two independent experiments with *Haliotis rufescens* postlarvae fed the diatom *Navicula incerta* were conducted in 10-mL vessels with daily water changes. Two factors were tested following split-plot experimental designs: six diatom densities (from 500–10,000 cells/mm²) and two light conditions (constant light at 19–33 $\mu\text{E}/\text{m}^2/\text{s}$ and darkness). Experimental units in darkness were kept inside black plastic bags but subjected to ~30 min of ambient light every day for maintenance. Food (*N. incerta*) was supplied as required to maintain diatom densities. The first experiment started with 14-day-old postlarvae and was conducted for 20 days; the second trial started with 2-day old postlarvae and was performed for 32 days. In general, postlarval growth increased as diatom density increased but stabilized at high densities (ca. >2,000 cell/mm²) and was significantly higher in darkness in both trials. In Experiment 1, average growth rate in darkness was 2.4 times higher than in light conditions (34.7 and 14.4 $\mu\text{m}/\text{d}$, respectively). In Experiment 2, average growth in darkness was 3.0 times higher than under constant illumination (14.4 and 4.8 $\mu\text{m}/\text{d}$, respectively). These results are discussed in terms of postlarval behavior and possible changes in the nutritional quality of diatom films. The potential implications for abalone culture are also addressed.

KEY WORDS: abalone postlarvae, survival, growth, darkness, diatom density

INTRODUCTION

The red abalone (*Haliotis rufescens*) is the largest abalone species in the world, reaching up to 28 cm in shell length (Hahn 1989, Leighton 2000). It represents 95% of the abalone culture in California (USA) (Leighton 2000) and is also the most important species cultured in Baja California, México (McBride 1998). Abalone culture is a high-risk activity and mortalities can reach up to 99% after 3 y (Hone et al. 1997). In the postlarval stage, which begins after settlement and metamorphosis, the highest mortality is usually reported (80% to 95%) (Searcy-Bernal 1996, Hone et al. 1997).

In abalone postlarvae, growth is influenced by several factors including type of food (Kawamura et al. 1998a, Roberts et al. 1999, Daume et al. 2000), quantity of food (Searcy-Bernal et al. 2001), starvation period (Roberts et al. 2001, Takami et al. 2000), temperature (Leighton 1974), and light intensity (Searcy-Bernal et al. 2003). For example, postlarvae of the blue abalone *Haliotis fulgens* grow better in low irradiances (6 $\mu\text{E}/\text{m}^2/\text{s}$) than in higher light intensities (24–75 $\mu\text{E}/\text{m}^2/\text{s}$), probably because of differences in ecologic conditions in the biofilms developed over culture surfaces (Searcy-Bernal et al. 2003). In the abalone farms of California and Baja California, postlarvae are usually maintained at irradiances from 3 to 200 $\mu\text{E}/\text{m}^2/\text{s}$ under natural photoperiods or continuous artificial light (Searcy-Bernal et al. 2003). Although the effect of photoperiod on postlarval growth is unknown, diatoms need light for their growth, which is important to maintain a good density of cells to feed the postlarvae.

Juvenile and adult abalones have a circadian rhythm; they are more active and feed at night (Hahn 1989, Leighton 2000). Some studies have shown increased growth rates when these gastropods

are cultured in darkness (Ebert & Houk 1984, Godoy-Corrales 1989). Research addressing this issue for postlarvae is lacking, although a preliminary study provided some evidence that postlarvae of *H. fulgens* increase their grazing rates at dusk (Vélez-Espino 1999).

Recent studies have shown that the quantity of food available for postlarvae is an important factor determining their growth. Grazing and growth rates of *H. fulgens* postlarvae increase as the density of the diatom *Navicula incerta* increases from 500 to 4,000 cells/mm² (Searcy-Bernal et al. 2001) but studies for other species are lacking.

The objective of this work is to evaluate the combined effect of continuous light or darkness conditions and different densities of the diatom *N. incerta* on the survival and growth of red abalone (*H. rufescens*) postlarvae.

MATERIALS AND METHODS

Abalone larvae were provided by the commercial farm Abalones Cultivados (Eréndira, B.C., México) on March and May 2002, transported to the Instituto de Investigaciones Oceanológicas (IIO) laboratory and used in Experiments 1 and 2, respectively. Competent larvae were induced to settle by adding 1.5 μM of gamma-aminobutyric acid (GABA) (Searcy-Bernal & Anguiano-Beltrán 1998).

Monocultures of *N. incerta*, a benthic diatom widely used to feed abalone postlarvae, were provided by the IIO Microalgae Laboratory. Diatoms were inoculated in 250 mL Erlenmeyer flasks containing 150 mL of *f/2* medium (Guillard 1975) and cultured under constant temperature (17 \pm 1°C) and illumination (37 $\mu\text{E}/\text{m}^2/\text{s}$, provided by fluorescent day-light lamps). After 3–4 days of culture, the flasks were immersed in an ultrasound bath (Fisher Scientific FS6) for 3 min to detach the diatoms, which were

*Corresponding author. E-mail: rsearcy@uabc.mx

counted using a hemacytometer to estimate cellular density and to calculate diatom densities to be used in the experiments.

Experiment 1

Settlement was carried out in plastic containers (57 × 37 × 13 cm) containing 5 L of filtered (1 μm) and UV-irradiated seawater. After metamorphosis, postlarvae were fed with *N. incerta* (250 cells/mm²) and cultured in these containers for 14 days. Seawater was changed every 2 days and diatoms were added every week.

The experiment was conducted in six-well tissue culture plates (Falcon 3046, 9.45 cm² bottom area) with 10 mL of 1 μm-filtered UV-irradiated seawater per well. Water changes were performed daily.

Two light conditions (light and dark) and six diatom densities were tested following a split-plot experimental design (Steel et al. 1997). Three culture plates (whole units) were placed inside thick black polyethylene bags to obtain dark conditions, and three plates were in continuous light of between 24 and 33 μE/m²/s (fluorescent day-light lamps). Six densities of *N. incerta* (250, 500, 750, 1,000, 2,000, and 3,000 cells/mm²) were randomly inoculated in the wells (subunits) of each plate. After 1 day, ten 14-day-old postlarvae (480 μm average shell length) were placed in each well. Water changes were performed daily. The culture plates in the dark treatment were exposed daily to light for ~30min during water changes.

After a week in these food densities all wells were cleaned of diatoms and feces with a brush and rinsed two or three times with seawater. Then, the wells were reinoculated with higher densities of *N. incerta* (500, 1,000, 2,000, 4,000, 8,000, and 10,000 cells/mm²). These final diatom densities were not applied during the first days of the experiment, because previous experience had shown deleterious effects of high densities on early postlarvae. Every 4 days, the wells were cleaned as described earlier and were reinoculated with these final diatom densities of *N. incerta*.

Experiment 2

The same experimental design and vessels were used, but some different procedures were followed. Competent larvae (13–15) were placed and settled with GABA in the wells of culture plates. Irradiance of the culture plates under continuous light was between 19 and 21 μE/m²/s. Sea water quality (1 μm-filtered, UV-irradiated) was further improved by sterilization (in an autoclave). Two days after metamorphosis induction postlarvae were fed with 6 densities of *N. incerta* (250, 500, 750, 1000, 2000, and 3000

cells/mm²). Every 4 days, the wells were cleaned and rinsed as described in Experiment 1 and reinoculated with these initial diatom densities. After 16 days (when postlarvae were 18-days old), reinoculation densities were increased to 500, 1,000, 2,000, 4,000, 8,000, and 10,000 cells/mm². These differences between experiments are summarized in Table 1.

Both experiments were conducted at 17°C ± 1°C. Survival was determined by counting live postlarvae in each well. To determine shell length and growth rates, all surviving postlarvae were video-recorded with a high-resolution camera (Sony SSC-C374) in an inverted microscope (Meiji Techno). Images were digitalized in a computer and measurements of shell length were performed with the program Scion Image (4.0.2). Survival and shell lengths were evaluated at days 9 and 20 in Experiment 1, and at days 10, 18, and 32 in Experiment 2 (in this trial day 0 corresponded to the day of the first diatom addition, i.e., 2 days after metamorphosis induction).

Statistical analysis was performed using the program JMP (version 3.2.6, SAS Institute Inc.). Split-Plot analyses of variance (ANOVA) (Steel et al. 1997) were used to evaluate the effect of diatom densities, light condition and their interaction on postlarval survival, shell length, and growth rates. When significant interactions were found, separate ANOVAs and multiple comparisons (LSD tests) were performed to evaluate the effect of diatom density within each light condition. Percent survival data were transformed before analysis (arcsine square root). A value of α = 0.05 was chosen as the significance level.

RESULTS

Survival

In Experiment 1, survival was high (>80%) in all treatments during the experimental period of 20 days (Fig. 1) and there were no significant over-all effects of diatom density or light condition, although in the first 9 days a significant interaction was found (Table 2) reflecting a different effect of one factor in levels of the other. Separate ANOVA tests within each light condition showed a significant effect of diatom density only in the dark ($F = 3.71$, $P = 0.029$) where a significantly lower survival in 2,000 cells/mm² was detected (LSD tests, Fig. 1).

In Experiment 2, survival after the 32-day experimental period was below 70% (Fig. 2). Treatment effects were not significant during the first 10 days; however, after 18 days a significant interaction was detected (Table 3). Survival in the dark was lowest

TABLE 1.

Differences between experiments. Both were conducted at 17 ± 1°C in sterile six-well tissue culture plates (10–15 postlarvae per well). Seawater was changed daily and reinoculations of diatoms at the experimental densities were performed every 4 days.

Procedure	Experiment 1 (March 2002)	Experiment 2 (May 2002)
Settlement (GABA, 1.5 μM)	In 51 containers	In wells
Seawater quality	1 μm-filtered, UV-irradiated	1 μm-filtered, UV-irradiated, sterilized
Irradiance at continuous light treatment	24–33 μE/m ² /s	19–21 μE/m ² /s
Initial age of postlarvae (after metamorphosis induction)	14 d	2 d
Low range of diatom densities (250–3,000 cells/mm ²)	At postlarval ages: 14–21 d	At postlarval ages: 2–18 d
High range of diatom densities (500–10,000 cells/mm ²)	At postlarval ages: 21–34 d	At postlarval ages: 18–34 d

Figure 1. Survival of *H. rufescens* postlarvae (mean \pm SE) in different light conditions and diatom densities in Experiment 1 during the first evaluation period (0–9 days) and the complete experimental period (0–20 days). Initial postlarval age was 14 days.

(45%) at the lowest diatom density (500 cells/mm²), increased as density increased up to 2,000 cells/mm² and remained more or less constant at higher densities (ca. 75%). In the light treatment survival was higher at intermediate diatom densities up to 8,000 cells/mm² (ca. 60%) but decreased drastically to 24% at the highest

density (10,000 cells/mm²) (Fig. 2). This survival was significantly lower than in the dark (76%) at the same diatom density ($F = 23.27$, $P = 0.008$). Similar survival patterns were observed at the final evaluation (32 days) (Fig. 2) when significant diatom and interaction effects were detected (Table 3). This interaction implied a significant effect of diatom density only in the dark ($F = 3.34$, $P = 0.040$), with the lowest survival (6%) at the lowest diatom density and more or less constant survival (ca. 60%) at densities above 2,000 cells/mm² (LSD tests). In this experiment survival was higher in dark conditions for most diatom densities. At the highest density (10,000 cells/mm²), final survival averages were 66% and 13% for the dark and light treatments, respectively, and this difference was significant ($F = 24.99$, $P = 0.007$).

Shell Length and Growth Rates

In both experiments, initial postlarval shell lengths were not significantly different among treatments. However, postlarval lengths and growth rates were significantly higher in darkness conditions at the end of the experimental periods.

In Experiment 1, final average shell lengths between 3,250 and 1,290 μm were obtained at the four higher diatom densities under darkness, corresponding to growth rates of 37–40 $\mu\text{m}/\text{d}$. In the light treatment the maximum length attained was 792 μm at 4,000 cells/mm² (15 $\mu\text{m}/\text{d}$) (Fig. 3, Fig. 4). This effect of light condition was already significant since the first evaluation (0–9 days, postlarval ages: 14–23 days) (Table 2). Diatom density did not have a significant impact on postlarval growth during the first 9 days but significant treatment and interaction effects were detected thereafter (Fig. 4, Table 2). At the end of the 20-day experimental period, diatom effects were significant only in the dark ($F = 23.60$, $P < 0.001$), showing an asymptotic behavior of growth after 2,000 cells/mm², whereas the slow growth (12–16 $\mu\text{m}/\text{d}$) in the light treatment was unaffected by diatom density ($F = 2.14$, $P = 0.130$) (Fig. 4).

In Experiment 2, the effect of light condition on postlarval growth was significant at the first evaluation and thereafter (Fig. 5, Table 3). A maximum final length of 1,084 μm (corresponding to a growth rate of 24 $\mu\text{m}/\text{d}$) was obtained in darkness at the highest diatom density (10,000 cells/mm²) and shell length decreased as diatom density decreased. In the light treatment a maximum final length of 546 μm was observed at 8,000 cells/mm² (7 $\mu\text{m}/\text{d}$) (Fig. 5, Fig. 6). Diatom density and interaction effects on growth rate were also significant from the first evaluation onwards (Table 3). At the end of the 32-day experimental period diatom effects were significant in both light conditions ($F = 11.96$, $P < 0.001$ and $F =$

DISCUSSION

Figure 2. Survival of *H. rufescens* postlarvae (mean \pm SE) in different light conditions and diatom densities in Experiment 2 during three evaluation periods. Initial postlarval age was 2 days.

6.16, $P = 0.005$ for darkness and light, respectively), following a similar pattern than in Experiment 1 with a marked suppression of growth below 2,000 cells/mm² in the dark and little effect of diatom density in the light treatment (Fig. 6).

Effects of Light or Dark Condition

Although a significant effect of light condition on postlarval survival of *H. rufescens* was not detected, the survival pattern in Experiment 2 (Fig. 2) suggests adverse effects of light at high diatom densities. Survival also decreased slightly at the highest diatom density in light conditions in Experiment 1 (Fig. 1) but this effect was not as sharp as in Experiment 2 probably because postlarvae were older and presumably more resistant to environmental stress. A similar pattern was observed in an experiment with *H. fulgens* where postlarval survival after 1 mo was 90% at 6 $\mu\text{E}/\text{m}^2/\text{s}$ and only 3% at 47 $\mu\text{E}/\text{m}^2/\text{s}$ (Searcy-Bernal et al. 2003). This might be related to oxygen supersaturation conditions in the boundary layer (postlarval microhabitat) at high diatom densities when light is available for photosynthesis.

Oxygen conditions in the boundary layers over diatom films can change dramatically according to light conditions. Searcy-Bernal (1996) detected 140% and 50% oxygen saturation over *Nitzschia* sp. films at 59 and 4 $\mu\text{E}/\text{m}^2/\text{s}$, respectively, and Roberts et al. (2000) report oxygen saturation values of 400% and 60% over *Achnanthes longipes* films under light and dark conditions. Although preliminary evidence suggests the abalone postlarvae can tolerate high oxygen concentrations (Loipersberger 1996), the concentrations reached at the highest diatom density in Experiment 2 under light conditions, might have been above the tolerance limits of early *H. rufescens* postlarvae.

On the other hand, the high survival and growth of postlarvae at high diatom densities under darkness, suggest that they can tolerate very low oxygen concentration (expected under such conditions because of oxygen consumption by diatoms) without adverse effects.

The effect of light conditions on postlarval growth was dramatic in both experiments. In Experiment 1, the average growth rate (over all diatom densities) in darkness was 2.4 higher than in light conditions (34.7 and 14.4 $\mu\text{m}/\text{d}$, respectively). In Experiment 2, average growth in darkness was 3.0 times higher than under constant illumination (14.4 and 4.8 $\mu\text{m}/\text{d}$, respectively). Searcy-Bernal et al. (2003) also report a positive effect of low irradiances, because postlarval growth of *H. fulgens* postlarvae was higher at 6 $\mu\text{E}/\text{m}^2/\text{s}$ than at 47 $\mu\text{E}/\text{m}^2/\text{s}$ (37 and 21 $\mu\text{m}/\text{d}$, respectively). This might be explained by differences in postlarval feeding behavior and/or ecological conditions of biofilms.

Adults and juvenile abalones have nocturnal feeding habits. Commonly during daylight hours abalones remain relatively quiet and tend to aggregate in darkened locations. Grazing activity begins about half hour before sunset and continues throughout the night to satiation (Leighton 2000). Several studies have shown an increase in feeding and growth rates when abalones are cultured in darkness (Ebert & Houk 1984, Godoy-Corrales 1989, Kim et al. 1997).

This pattern has not been documented for postlarvae, which are generally assumed to feed all day because they do not seem to have the same negative phototactic behavior as juveniles and adults. However, this may not be true and nocturnal feeding habits might be established during the postlarval stage. Vélez-Espino (1999) evaluated grazing rates of *H. fulgens* postlarvae during a 24-h cycle and found increased feeding about an hour before sunset in 15- and 30-day-old postlarvae, which is consistent with the feeding behavior of larger abalones. In the experiments reported here, a higher fecal production was qualitatively observed in the darkness

treatments during the cleaning procedures, which is consistent with the hypothesis of increased feeding under dark conditions, which would in turn increase postlarval growth.

Light conditions might have an impact on ecologic conditions or nutritional value of the biofilm affecting postlarval growth. An important nutritional source for abalone postlarvae is provided by the mucus produced by diatoms and bacteria in the biofilm (Kawamura & Takami 1995, Kawamura et al. 1998a). This mucus is

composed of extracellular polymeric substances (EPS) (Decho 1990), which are produced at a higher rate in darkness than under light conditions by the benthic diatom *Navicula perminuta* (Smith & Underwood 2000). This suggests that an increased nutritional value of diatom films under darkness might help to explain the higher growth rates of abalone postlarvae. On the other hand, ecologic conditions in the boundary layer in the light treatment might have limited postlarval growth (Searcy-Bernal 1996).

Figure 4. Growth rates (mean ± SE) of *H. rufescens* postlarvae in Experiment 1 during different age intervals.

Effects of Diatom Density

Diatoms should be available in enough quantities to produce good growth of abalone postlarvae, but very high diatom densities may have a negative impact on postlarval growth because of extreme oxygen concentrations and/or other ecologically adverse conditions (Ebert & Houk 1984, Searcy-Bernal 1996). Therefore, higher survival would be expected at intermediate diatom densities as observed in Experiment 2 under illumination (Fig. 2). However, high diatom densities under darkness did not have a negative impact on postlarval survival as discussed earlier (Fig. 2). High sur-

vival (>60%) has been reported for postlarvae of *H. discus hannai* and *H. iris* fed different diatom species at densities between 1,000 and 4,000 cells/mm² (Kawamura & Takami 1995, Kawamura et al. 1998a).

Although the effect of diatom density on initial postlarval growth was not significant in Experiment 1 (Fig. 4, Table 2) where the initial postlarval age was 14 days: a significant effect was found in Experiment 2 (Fig. 6, Table 3), where the initial postlarval age was 2 days. Growth of these newly settled postlarvae increased most markedly as diatom density increased up to 1,000 cells/mm², and this effect was stronger under darkness. Probably this reflects the benefit of increased diatom mucus and associated bacteria in the biofilms as diatom density increases, since early postlarval growth does not depend on the direct digestion of diatom cells (Kawamura et al. 1998b).

The growth of older postlarvae responded to higher diatom densities following similar patterns in both trials. The second growth period evaluated in Experiment 1 (Fig. 4) started with 23-day-old postlarvae and is comparable to the third evaluation period (Fig. 6) in Experiment 2 that started with 20-day-old postlarvae. In both cases growth rates in darkness increased sharply as

Exp. 2: Light

Exp. 2: Darkness

Figure 5. Shell length (mean ± SE) of *H. rufescens* postlarvae at different ages in the experimental light conditions and densities of *N. incerta* in Experiment 2.

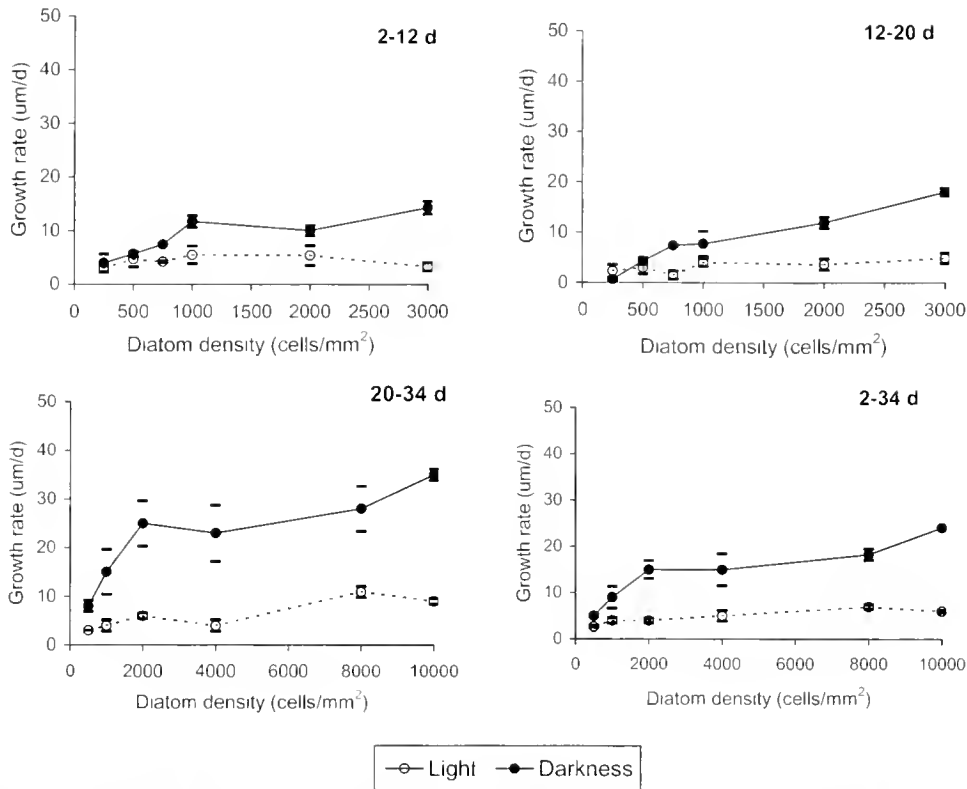

Figure 6. Growth rates (mean \pm SE) of *H. rufescens* postlarvae in Experiment 2 during different age intervals.

diatom density increased up to 2,000 cells/mm² and leveled off at higher densities. This suggests a possible optimum diatom density to feed *H. rufescens* postlarvae of these ages under darkness.

Under continuous illumination very little effect of diatom density on postlarval growth was observed in both experiments. This contrasts with the results of Searcy-Bernal et al. (2001) who showed that 15- and 30-day-old postlarvae of *H. fulgens* kept at between 17 C to 19 C and $\sim 50 \mu\text{E}/\text{m}^2/\text{s}$, increase their growth as *N. incerta* density increases up to 2,000 cells/mm². This difference might be due to several factors including experimental conditions, postlarval, or interspecific differences.

Survival and postlarval growth in Experiment 2 were lower than in Experiment 1, probably because of differences between larval batches or experimental conditions. Variability in abalone growth is common even within the same batch (Hahn 1989) and differences in postlarval growth of *H. rufescens* between batches similar to those observed here have been reported in other studies (Martínez-Ponce & Searcy-Bernal 1998). On the other hand Experiment 1 started with older postlarvae cultured under optimal conditions before the trial was conducted.

The main conclusion of this work is that the growth of abalone postlarvae might be dramatically improved if they are cultured in darkness. Large-scale trials under hatchery conditions are required to determine if this result can be extrapolated to production. The potential implications of these findings to postlarval culture would depend on a reliable source of cultured diatoms to reinoculate tanks as required, which is not currently a technical problem (Roberts et al. 2000).

ACKNOWLEDGMENTS

The authors thank the commercial farm Abulones Cultivados (Eréndira, B.C., México) for the donation of abalone larvae, Enrique Valenzuela (I.I.O.) for providing the monocultures of *N. incerta*, Casandra Anguiano-Beltrán for her technical support, Carmen Paniagua-Chávez, and two anonymous reviewers for their critical comments on the manuscript. This study was partially funded by the University of Baja California (grants 4040 and 4403) and the Mexican Government (CONACYT grant 37461-B and SNI grant 5532). This paper is part of the doctoral dissertation of E. Gorrostieta-Hurtado supported by a CONACYT scholarship.

EFFECTS OF DENSITY AND FOOD SUPPLY ON POSTLARVAL ABALONE: BEHAVIOUR, GROWTH AND MORTALITY

ROB DAY,* PATRICK GILMOUR, AND SYLVAIN HUCHETTE

Zoology Department, The University of Melbourne, Parkville, Victoria 3010, Australia

ABSTRACT Understanding density dependent processes in abalone is important for sustainable management of fisheries, and optimum aquaculture production. Density and food were manipulated to test their interacting effects on the growth and survival of hatchery produced postlarval *Haliotis rubra*. Feeding and dispersive behavior was also examined. Initial densities ranged between the densities used in aquaculture and those reported in the natural environment. Higher initial density increased the mortality rates of postlarvae in two experiments. Simultaneous manipulation of diatom food supply and density showed that the effect of density on mortality was mostly independent of food. Growth was strongly related to food supply, but also significantly reduced by high initial density, and these effects were additive. When diatom density was low, postlarvae did not increase rasping rates so the effect was that food was consumed more slowly. This explains the strong effect of food supply on growth. No aggressive interactions between feeding postlarvae were observed, but they graze intensively, leaving small distinct patches that have been cleared of algal food. Postlarvae encountering patches without food move rapidly and apparently randomly in search of food. The dispersal rate of postlarvae increased with density, presumably because post larvae spent more time searching for food. This searching is likely to be energetically expensive, and would increase at high densities because more cleared patches are created. This may explain why high initial densities of postlarvae had persistent reduced growth even when food was abundant, but does not explain the increased mortality at high density irrespective of food supply. We hypothesize that this effect may be attributable to other factors, such as the increased transmission of a pathogen at high density.

KEY WORDS: recruitment variability, intraspecific competition, density dependence, diatoms, *Haliotis rubra*

INTRODUCTION

The role of density dependent processes in populations has been an important debate in ecology for decades (Nicholson 1933, Andrewartha & Birch 1970, Stubbs 1977, Rose et al. 2001). Understanding any density dependent processes throughout the life cycle is also vital to sustainable management of exploited populations (Fogarty et al. 1991, McShane & Naylor 1995), because the overall compensatory density dependence in the relation between adult population size and future recruitment is crucial for any sustainable fishery (McGarvey 1996, Rose et al. 2001). Density dependent processes will also determine the optimum production strategies in aquaculture.

Although it is understood that some form of density dependence must operate in all populations (Haldane 1953), recruitment to some fish and invertebrate populations is so highly variable that some have questioned whether any relation exists between adult stocks and recruitment (e.g., McShane 1995, McShane & Reyn 1996). There is general agreement that the early life history stages of these organisms are a likely source of much of the variation in recruitment, due to their small size and relatively large numbers (Hunt & Scheibling 1997). This may make them particularly vulnerable to density dependent processes such as predation (Hurlbut 1991, Shepherd & Daume 1996), competition for food (Marshall & Keough 1994, Schmitt 1996, Elmgren et al. 2001), or space (Paine 1984).

Both pre- and postsettlement stages may contribute to recruitment variability, but the early postsettlement period has not received much attention, due to the difficulty of measuring small settlers whose distribution varies greatly in time and space (Keough & Downes 1982). Measuring recruitment at some arbitrary minimum size may ignore mortality that could have occurred in the period between settlement and observation (Keough & Downes 1982, Connell 1985). In cases where settlement rates are

high (Gaines & Roughgarden 1985, Hurlbut 1991, McShane 1991) or mortality rates vary over time (Roegner 1991) postsettlement processes will be more important in determining the degree of recruitment variation than larval supply. Further, the significance of the postsettlement period is likely to be especially important in populations where larval dispersal is relatively local, because the dynamics will correspond to a closed rather than open population model (Roughgarden et al. 1988, Underwood & Fairweather 1989). In closed populations the postsettlement phase will both depend on and, with a time lag, impact on adult population density, because larval influx from other populations will not confuse the relationship.

In aquaculture the rate at which a farm can produce abalone of any given size will depend directly on the survival and growth rates of postsettlement individuals. Thus, understanding any density-dependent processes that affect growth and survival is essential for determining the most effective strategies to maximize yield and minimize turnover rates and costs in aquaculture ventures.

Abalone are ideal for examining density dependent mechanisms in the postsettlement phase, because they are now extensively cultured. The issue is important because effective management arising from an understanding of the processes underlying recruitment variation is vital to the sustainability of these fisheries (Shepherd & Rodda 2001), and there is evidence that many abalone species have localized larval dispersal (Prince et al. 1987, Prince et al. 1988, McShane et al. 1988), so that populations are effectively closed. Studies on several species have indicated that various density dependent processes may act in the early postsettlement stage. These include competition for space (McShane 1991), predation (Shepherd & Daume 1996, Preece et al. 1997), and competition for food (Daume et al. 2001, Heasman et al. 2001). While these studies show evidence for density-dependent growth or mortality, the underlying mechanisms remain obscure.

The lack of a mechanistic understanding of early life history processes can be associated with the inherent difficulty in studying tiny individuals in the field (McShane 1992). Using a suction-

*Corresponding author. E-mail: r.day@unimelb.edu.au.

sampling device McShane (1991) sampled postlarval *Haliotis rubra* in the crustose coralline red algal habitat, where abalone larvae settle almost exclusively (Shepherd & Turner 1985, Shepherd & Daume 1996, Daume et al. 1999). Over time, the results showed a change in mortality rate that was correlated to the number of postlarvae observed soon after settlement. Shepherd & Daume (1996) obtained similar results from an *in situ* study of *Haliotis laevigata* and *Haliotis scalaris*. The limitation of these approaches is that they are observational rather than experimental so that their conclusions are limited to inferences or suggestions.

Ignorance of the underlying processes behind density dependent mortality and growth extends to the hatchery environment. Because the effects of food quality and postlarval diet on growth and survival have received much attention in the recent literature, (e.g., Kawamura et al. 1998a, Kawamura et al. 1998b, Roberts et al. 1999a, Daume et al. 2000), the role of density in this has only recently been recognized (Daume et al. 2001, Heasman et al. 2001). This is surprising considering that improved settlement rates using cues such as the green alga *Ulveella lens* (Daume et al. 2000, Daume et al. 2001) allow very high densities of postlarvae to be cultured. Even this recent work on postlarval density only describes the outcomes of the interaction (in terms of the effects on growth and survival). The same problem as in field studies is evident: while competition for food is proposed, the mechanisms remain untested.

The objective of this study is to identify the mechanisms behind any density dependent effects on growth and survival rates of postsettlement abalone. Identifying these mechanisms might both allow abalone farms to increase their efficiency, and prove useful in predicting the dynamics of natural populations. Small-scale experiments in a hatchery environment and observations of postlarval behavior in relation to food were used to test for intraspecific competition for food in postlarval *H. rubra*, and to investigate the underlying mechanism of any density effects. The postlarval phase in abalone has been defined as the period after settlement and metamorphosis (~300 μm shell length) to the formation of the first respiratory pore (e.g., Leighton 1974, Kawamura et al. 1998b). This seems arbitrary in an ecologic context. In this study the end of the postlarval phase is considered to be the shift to the cryptic juvenile phase at between 5- and 8-mm shell length (Shepherd & Turner 1985, Shepherd & Daume 1996), which involves a change in habitat and behavior that will influence the resources they use and sources of mortality. In the hatchery environment postlarvae are weaned off microalgal food and onto artificial food at a similar size (Hahn 1989).

METHODS

Spawning was induced in conditioned brood stock at the hatchery of Ocean Wave Seafoods, Lara, Victoria. Larvae were kept in an aerated, 300 L conical tank with flowing UV-sterilized, 3- μm filtered water. Larvae were used in experiments 5–6 days after fertilization, when they were judged competent to settle, as they began exploring the tank's surface and had developed the third tubule of the cephalic tentacle (Daume et al. 2000). The experiments used two larval batches, each the result of a mix of four to six parents.

A culture of the diatom *Navicula* sp., obtained from the Department of Fisheries, Western Australia, was used as food in all experiments. *Navicula* sp. has been shown by Daume et al. (2000) to produce high growth and survival rates in postlarval *H. rubra*.

The non-axenic culture was maintained in *f/2* growth medium complemented with silicates (Guillard & Rytner 1962) at ambient temperature and under a 12 h L:D photo cycle. For the *f/2* growth medium, seawater was filtered to 1 μm before adding sodium hypochlorite (commercial chlorine, 12.5% W/V) and aerating for 3 h. A neutralizing solution of sodium thiosulfate was then added, followed by a further 3 h of aeration.

Behavior

Ten Petri dishes (85 mm diameter) were inoculated with *Navicula* sp. and cultured for 3 days, after which diatom density was measured by counting the number of diatoms within a 300- \times 300 μm quadrat at $\times 100$ magnification for 10 random fields in each dish. Mean density was 517 mm^{-2} (SE = 24, n = 10). Isolated square patches of food approximately 5 \times 5 mm were formed by removing a 5-mm wide grid of diatoms with a small cloth. A single postlarva (mean size 1273 μm , SD 200 μm , n = 12) was placed in the center of one of these patches in each dish, and its position recorded every 4 h for a 24 h period (under a 12 h light to dark cycle).

Effect of Density on Dispersal

Plates with a cover of the green alga *Ulveella lens* of at least 95% were used to examine the grazing behavior of postlarvae. A good cover of *U. lens* greatly enhances the settlement rate of *H. rubra* larvae and provides food to larger postlarvae (Daume et al. 2000, Daume et al. 2001, Daume et al. 2004). Squares (200 \times 200 mm) cut from commercial settlement plates (30 \times 60 cm) were placed horizontally in a 225 \times 225 \times 145 mm container filled with 3- μm filtered seawater with an average output of 80 \pm 5 $\text{mL}\cdot\text{min}^{-1}$ per container. Overhead fluorescent lights provided illumination on a 12 h cycle and temperature remained at 18 $^{\circ}\text{C} \pm 1$ $^{\circ}\text{C}$.

At settlement, the larvae were restrained to the center of the plates with a vertical PVC pipe, 45 mm in diameter and 16 cm high. After settlement, the pipe was removed and the larvae were allowed to spread. A grid with concentric squares (Fig. 1) was placed behind the settlement plates and the number of postlarvae within the central square was manipulated by haphazardly removing some of the postlarvae with a soft cloth to obtain high (~100) and low (~20) densities. All post larvae outside this central square were removed with a soft cloth. Five replicates were used for each treatment. The distribution of the postlarvae was then recorded by counting the individuals in each marked square of the grid at 1.5, 6, 12, 24, 48, 96, and 192 h after the removal of the pipe.

Density-light Interaction

Two levels of initial postlarval density (20,000 and 5,000 m^{-2}) were tested and the abundance of diatom food was controlled using 2 levels of illumination (one layer of shade cloth and no shading). Higher illumination maintains a higher diatom productivity and abundance (Kinne 1973), so that light management is a common method in commercial hatcheries to control algal abundance on settlement plates (Daume et al. 2001). The higher initial density was chosen according to the highest densities found in the natural environment (McShane 1991, McShane & Smith 1991, Nash et al. 1995) and the scale of the experimental units. Whereas 20,000 individuals m^{-2} is c.a. 1.6 times greater than the maximum recorded in the wild (McShane & Smith 1991) their sampling technique examined density on the scale of m^2 and small, denser aggregations may occur on a smaller scale—such as that used here.

Figure 1. Grid used to assess the distribution of postlarvae during the dispersal experiment on *U. lens* covered plates. At the start of the experiment, postlarvae were restrained to the central square (A). Thereafter, counts were carried out in each area until 192 h after the postlarvae were allowed to disperse across the plate.

The lower initial density corresponds to that used in the aquaculture industry (Heasman et al. 2001), and was judged sufficient to ensure that a minimum number of postlarvae survived in each jar after settlement and initial mortality, two processes that are notoriously variable.

Commercial plastic settlement plates (30 × 60 cm) were cut into squares (5 × 5 cm). These plates had a cover of the green alga *Ulva lens* of at least 95%. Plates were then randomly assigned to glass jars (c.a. 250 mL volume) filled with 3 μm filtered seawater. The jars were placed 35 cm below a fluorescent neon light on a 12 h L:D cycle. Approximately 300 larvae were added to each jar. There was no flow at this stage. Three days after the larvae were released the plates were examined under a dissecting microscope. The initial treatment densities were established by haphazardly removing postlarvae from the plate until the desired number had been reached. After this manipulation, numbers were recounted to ensure accuracy. A flow-through system of 3 μm filtered seawater was turned on at this point.

Opaque PVC piping was placed around all jars to restrict illumination to that coming from above. In the shaded treatments, 70% shade cloth was fastened over the top of the PVC piping. Six replicates were used for each of the four treatment combinations. Survival and growth were monitored weekly for a period of 6 wk. For sampling, platelets were carefully transferred to a petri dish under the dissecting microscope and were kept immersed in water at all times. The postlarvae were counted, and seven randomly selected postlarvae were measured at ×50 magnification with a graticule (±20 μm resolution). The jars were wiped clean after each weekly measurement to minimize disturbance. Average flow rate was also recorded for each outlet of the system. Because the counts were obtained repeatedly from plates over time, differences in overall mortality of post larvae between initial density treatments were tested using linear comparisons of means in a repeated measures ANOVA. We chose this method rather than survival

analysis because it is more familiar to most ecologists and the interpretation is straightforward.

Food quantity and quality

Food abundance (high and low) and initial postlarval density (20,000 and 3,500 m⁻²) were manipulated to test their combined effects on growth and survival. In the density-light experiment, food quantity and quality could not be closely monitored because diatoms could not be clearly seen through the dense *U. lens* cover. This second experiment was designed to directly manipulate and monitor the food levels and was thus carried out in petri dishes inoculated with a diatom film. The petri dishes were randomly placed under a fluorescent light (12 h L:D cycle), and water was exchanged with sterile, 3 μm filtered water every 2 days. The experiment was run for 3 wk.

Small petri dishes were used (20, each 3.4 cm diameter, 9.1 cm² area) and a diatom film of *Navicula* sp. was grown on them before the start of the experiment. Diatom abundance was controlled in two ways. Half of the petri dishes were inoculated 4 days prior to the others to allow for a denser initial diatom biofilm. This difference was then maintained by the addition of extra diatoms to the dishes (1–2 times per week). Five replicates were used for each of the four treatment combinations.

Post-larvae were grown at low density on large (20 × 20 cm) *U. lens* plates in a 3 μm flow-through system and then transferred 16 days after settlement to the petri dishes at a mean size of 663 μm ($n = 118$, SD = 70 μm). Transferral involved brushing them off the plates into a clean petri dish with a soft cloth. They were left for 3–4 h and rinsed several times with 3-μm filtered, sterilized seawater to remove diatoms, fecal material, and the like. They were then delicately moved into the treatment dishes with a soft cloth. Damaged shells were removed and postlarvae that did not land the right way up were inverted with a small jet of water from a pipette.

Survival was checked 1, 3, and 7 days after transferral to the petri dishes and every week thereafter. The initial size of all post-larvae in the low-density treatments and 8 randomly selected post-larvae from the high initial density treatments were measured on the second day at ×50 magnification. Diatom abundance was measured at the same time with a compound microscope. Ten fields of view at ×100 magnification were randomly selected and the number of diatoms within a 500 × 500 μm grid was counted along with an estimate of percent coverage. Growth, survival, and diatom abundances were measured weekly.

RESULTS

Behavior and Patchy Food

Postlarvae generally began grazing less than 20 sec after being transferred to a patch of food. Rasping of the surface with the radula could be observed with an inverted compound microscope and diatoms could be seen being removed by the postlarvae.

Grazing behavior of postlarvae consisted of steady rasps of the surface. After each rasp the postlarvae turned a small angle in one direction. This direction was the same until the abalone had turned approximately 120°, as shown in Figure 2. A small movement forward was made to maintain its position on the edge of the food before grazing continued in the opposite direction. Postlarvae grazed areas thoroughly and in a manner that formed bare patches of space.

Figure 2. Movement patterns of postlarvae grazing on densely covered diatom surface.

The mean grazing rate of postlarvae was 1177 ± 113 diatoms hour^{-1} in patches of diatoms ($n = 10$). There was no significant linear regression of size on grazing rate ($F_{1,8} = 1.869$, $P = 0.209$). Observations showed that less food is consumed per unit time when diatom densities were low. Where diatoms were closer together, each rasp of the radula picked up more diatoms than when the diatoms were more widely spaced. When diatom density was minimal (approximately 50 mm^{-2}) the radula would only pick up diatoms every three to four rasps, as opposed to every one to two rasps at higher diatom densities. There was no obvious increase in rasping rate of the radula at lower diatom densities, which suggests that postlarvae do not compensate for a lower diatom density by grazing faster.

Post-larvae would often graze to the edge of patches of food. In doing so, their anterior sensory appendages lost contact with the food source. In the absence of this contact postlarvae would stop grazing and start a series of apparently random turns, often more than the 120° rotations observed when grazing. Their speed of movement also increased. This pattern of movement ceased when the postlarvae found another patch of food. Three postlarvae were observed from the time they stopped grazing to the time they found a patch and started grazing again. This occurred in a mean time of 105 ± 34 sec. Seven postlarvae were observed to leave their patch over the 28 h of the experiment. This would commonly occur before the entire patch had been consumed (mean cover remaining = $43 \pm 4\%$, $n = 7$). This does not include the postlarvae that may have traveled between patches between observation intervals. Contacts between postlarvae were observed in the other experiments, but there was no aggressive interaction; searching or grazing often continued throughout the contact.

Dispersal

Figure 3 shows the distribution of postlarvae in each concentric region expanding from the center of the plate. Postlarvae started spreading immediately and a change in distribution was observed within $1/2$ h. The movement of postlarvae out of the central zone appeared faster at higher initial densities. Towards the end of the experiment, when significant numbers of postlarvae were reaching the larger outer areas of the plate, the proportions became more even across the plate at high rather than at low initial density (Fig. 4), although the proportion of postlarvae remained highest in the central area.

The Effect of Shading and Density

Figure 5 shows the change in size and the trend in log numbers surviving for the postlarvae in each of the four treatments over

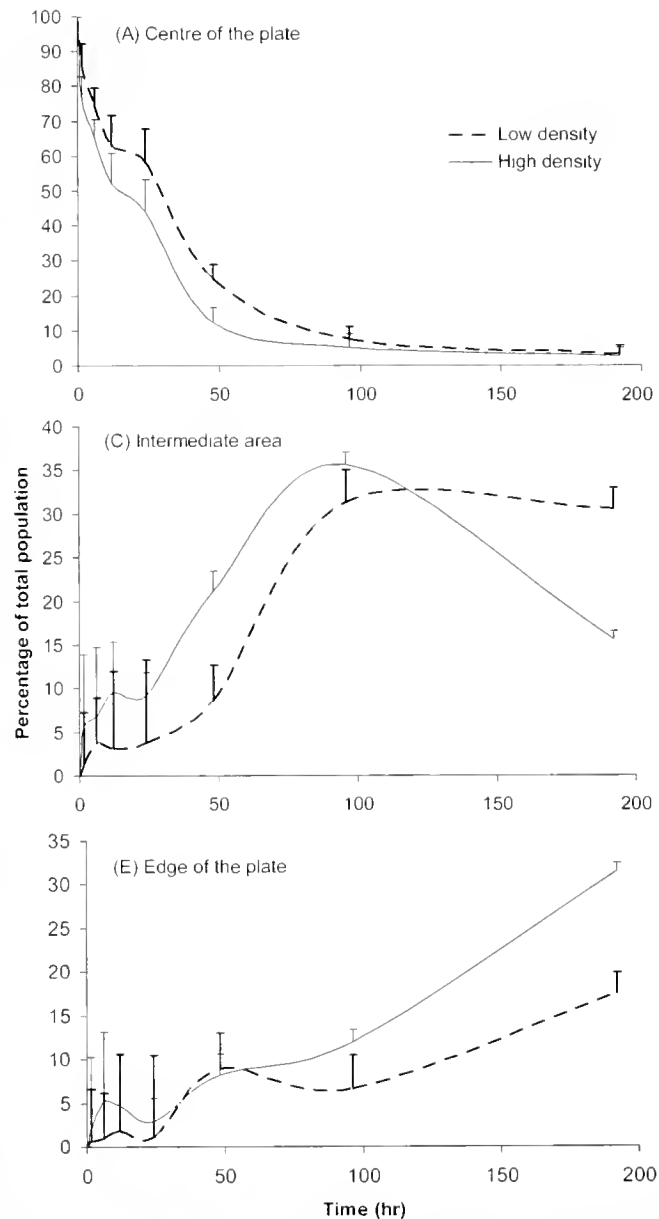

Figure 3. Dispersal of postlarvae over time on square plates covered with *U. lens*. Proportions of the population in 3 distinct areas (A, C, & E) of the plates are presented.

time. Although variation in survival within treatments was high, there was a significant interaction between time and density (Table 1), and the linear component of this interaction was significant ($F_{1,20} = 8.498$, $P = 0.009$). Thus overall mortality was significantly affected by the density treatment. There was no significant time by light interaction, which indicates that mortality is independent of the shading treatment. There was no significant difference in flow between treatments (Light: $F_{1,20} = 0.692$; Density: $F_{1,20} = 0.126$; interaction $F_{1,20} = 1.203$; $P > 0.20$ in all cases).

Analyzing the size data for the whole experiment duration would have greatly reduced the replication level in the ANOVA with repeated measures, due to the mortality of all postlarvae in some of the experimental units. Therefore only the data from the first 2 wk of the experiment were analyzed this way. In weeks 0–2 postlarvae became significantly larger in the unshaded treatments

Figure 4. Density of postlarvae in each area of the plate after 192 h. A-F refer to areas of the plate shown in Figure 1.

(Table 1, Fig. 5B). There was also a trend towards smaller sizes in the high initial density treatments (Fig. 5B). This trend became significant after 5 wk (Density: $F_{1,9} = 9.80$, $P < 0.05$; Light: $F_{1,9} = 2.92$, $P = 0.12$, Interaction: $F_{1,9} = 0.407$, $P = 0.54$) despite the loss of replication.

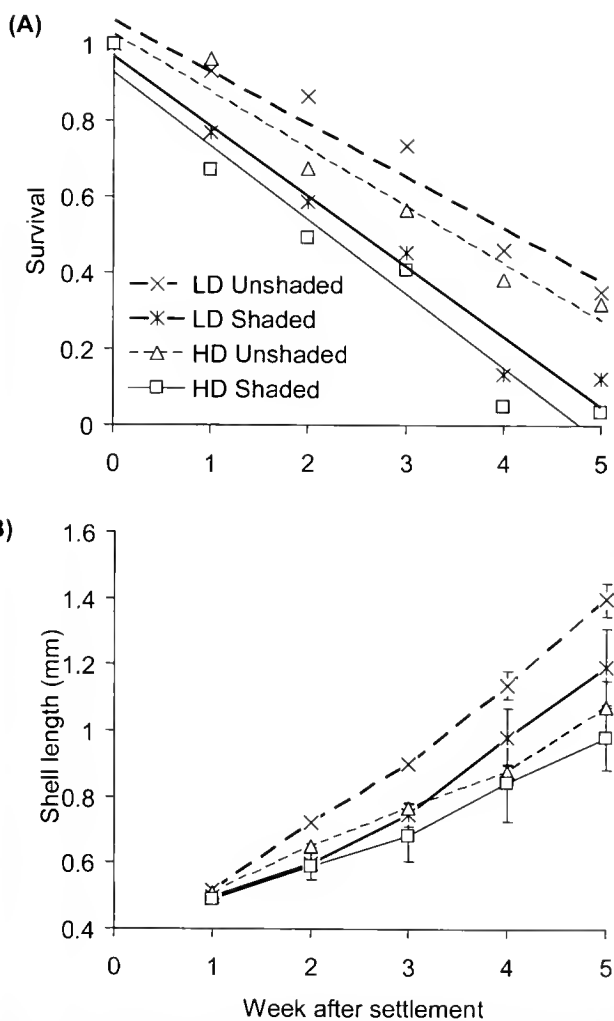

Figure 5. Survival (A) and growth (B) of postlarvae kept at 2 levels of density on shaded or unshaded plates covered with *U. lens* and diatoms.

TABLE 1.

Food Quantity and Quality

Food abundance varied between treatments, as shown by the analysis of diatom densities (Table 2). Interestingly, while there was no significant three-way interaction with time, there was a significant interaction between density and food level. From Figure 6C, this seems to stem from the fact that diatom abundance differed more between densities at the high food level, than between densities at the low food level. Diatom abundance increased over time in the high food level treatments but was fairly constant in the low food treatments, which explains the time by food interaction. The smaller time by density effect is due mainly to the slower increase of diatom abundance in the high food treatment where density was high. Presumably this merely reflects the faster consumption of diatoms in this treatment.

The effect of food level and initial density on postlarval survival is shown in Figure 6A. For the first 14 days there was a steady decline of postlarval numbers in both high-density treatments, compared with a low and stable mortality rate in the low-density treatments. These trends seem to be independent of food availability. The repeated measures ANOVA (Table 2) reflects this pattern, as the food by time interaction and the three way interaction were not significant, whereas the time by postlarval density interaction was highly significant. From day 14–21 however, postlarval numbers also sharply decreased in the low-density treatment with excess food (Fig. 6A).

The growth of postlarvae differed significantly between density treatments and between food treatments (as shown by the time by density, and time by food tests in Table 2). Postlarvae in the low density and high food treatment were the biggest, whereas those at high initial density, but low food, were the smallest (Fig. 6B). There was no significant interaction between food and initial density (or three factor interaction with time), indicating that food level and initial density have additive effects on postlarval growth.

DISCUSSION

Behavior

There are several aspects of the observed grazing behavior of the postlarvae that seem to be important in explaining our results

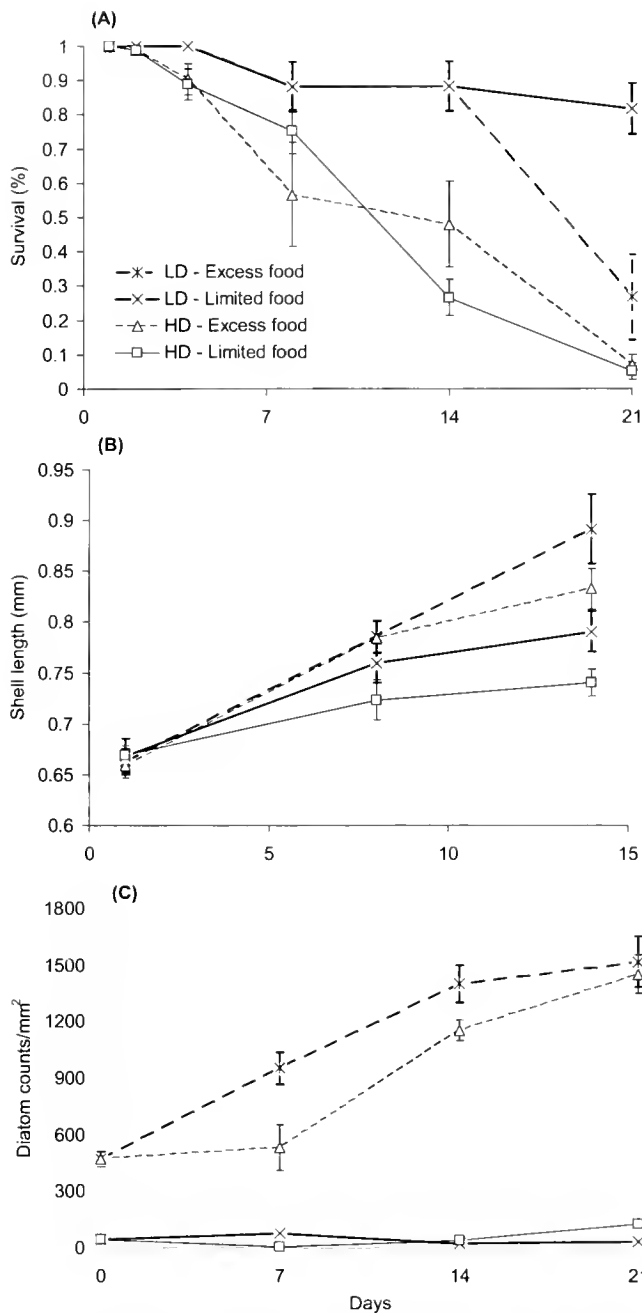

Figure 6. Effect of food quantity and postlarval density on (A) survival and (B) growth in petri dishes covered with *Navicula* sp. (C) shows the changes in density of diatom cells for the 4 different treatments over time.

and results from other experiments on abalone postlarvae by Daume et al. (2004). First, postlarvae within a patch of food were efficient grazers, removing the majority of diatoms present, so that they created small patches cleared of food. Second, food consumption in a patch appears to vary directly with diatom density. Third, postlarvae that encountered areas without food began what appeared to be a random search pattern, with rapid movements.

Rapid movement in abalone and other gastropods has been shown to be a significant energetic cost (Donovan et al. 1999). This may be due to the high levels of anaerobic respiration in-

volved, or the costs associated with mucus production for movement (Denny 1980), so that increased movement will have a significant impact on the balance between nutritional intake and energetic output (Carefoot 1987). This balance may be specially delicate in postlarvae, as compared with adults, because of the greater energetic costs associated with a large surface area to volume ratio as well as rapid morphologic development (Roberts et al. 1999a, Roberts et al. 1999b). As substantial time is spent in grazing even a small patch of algae, the time required to search for a patch may only be a small proportion of the total time spent consuming it. Nevertheless, in areas where patches of food are scarce, the sum of these erratic movements must be a significant energetic cost for the postlarvae, and impact on health and performances.

Postlarvae did not search for denser patches of diatoms. This is consistent with observations of other marine grazers and indicates an opportunistic approach to foraging (Hawkins & Hartnoll 1983). Random patterns of movement were also observed in the dispersal of postlarvae from the center of horizontal plates. If dispersal was based on the availability of food, then one might expect that postlarvae would move out in a noticeable "wave" as food became depleted in the center of the plate. The spread across the plate, with a higher proportion at the center even after 192 h, suggests instead a more random movement that was independent of food density. Dispersal was faster at higher initial densities of postlarvae. This pattern can be explained by our behavioral observations. Postlarvae at high density presumably more often encountered patches grazed by other postlarvae, which would lead to more time spent moving and thus a faster dispersal.

Similarly, postlarvae in high-density treatments would encounter many grazed patches, leading to relatively costly rapid movements. Where diatoms occur in patches of high and low density, postlarval nutrition may be even more variable, because some would spend long periods grazing areas with low food density. This food situation is likely to arise when an area has been grazed some time previously. Diatoms would have started to recolonize the grazed patches, but would not be at high density. It seems obvious that the more pregrazed areas encountered by the postlarvae, the lower the energy intake in proportion to the costs to the postlarvae.

Behavior may explain the distribution of postlarvae within the hatchery environment. Postlarvae are often grown on vertical plates covered in microalgae (Hahn 1989). Our observations of blacklip abalone on these plates a few weeks after settlement indicate a higher density on the top of the plates compared with the bottom. The top parts of the plates receive more light and are therefore likely to have denser food. Towards the bottom, grazed patches would not be quickly recolonized by diatoms, so that postlarvae may spend less time grazing in these areas. Their rapid searching would lead to dispersal from the lower parts of plates, whereas those at the top would spend more time grazing and thus move slowly. We cannot discount taxes in response to light or gravity, but in the natural environment postlarvae are found on crustose coralline algae that often have very rugose or uneven surfaces, and they occur on the tops or sides of rocks (McShane 1991, Shepherd & Turner 1985, Shepherd & Daume 1996). Thus, light and gravity may not be reliable cues to find food in natural situations.

Effect of Density on Postlarval Growth

As larvae from different batches may differ in quality (Martinez & Searcy-Bernal 1998, Daume et al. 2000), direct compari-

TABLE 2.

Repeated measures ANOVA of diatom density (day 0–21), logged post-larval counts (day 0–21) and mean size (day 0–14), testing for the effects of density and food levels. Probabilities were adjusted using the Greenhouse-Geiser statistic.

Source of Variation	Diatom Density			Survival (Log Nos)			Mean Size		
	df	MS	F	df	MS	F	df	MS	F

sions between batches must be examined with caution. Nevertheless, the mean size reached by postlarvae was negatively affected at high initial densities in both experiments. There are several mechanisms by which density could cause changes in postlarval size distributions. If size-dependant mortality was occurring, the death of smaller (or larger) individuals would skew the size distribution of the remaining postlarval population. This would give the impression of different growth rates between treatments. Because size-frequency distributions in the present experiments seemed normal, their small scale and the small number of individuals measured in each population prohibit definitive conclusions. Normal size distributions are usually observed in well-fed populations in the hatcheries however (Huchette 2003) suggesting that size-dependent mortality is unlikely, and the size differences reflect different growth rates.

This difference in growth rates continued to the end of the experiment despite the fact that differences in density between treatments were reduced by higher mortality in the high initial density treatments, so that densities were similar by the end of the experiment. A negative relationship between growth and density suggests there is density-dependent intraspecific competition for space or food (Stimson 1970, Branch 1975, Hughes 1986, Jarayaband & Newkirk 1989, Parsons & Dadswell 1992, Foster & Stiven 1996). Direct competition for food has been shown for several marine gastropods (e.g., Stimson 1970). These are often limpets defending patches of algae near their home scars (Chapman & Underwood 1992). Direct competition is unlikely in abalone postlarvae due to their free-ranging foraging behavior, and no observations of aggressive confrontations were made throughout this study. The competitive interactions are therefore likely to be indirect.

Exploitative (indirect) competition for food has been shown in numerous benthic marine invertebrates, particularly herbivorous gastropods (Creese & Underwood 1982, Marshall & Keough 1994). It usually occurs when the abundance of a resource is depleted by consumers, and as a result this resource becomes limiting (Schmitt 1996). Food was a limiting factor because it significantly affected growth in both experiments. But even when food was clearly in excess in one of these experiments, the effect of density on growth appeared to have the same negative effect. It

seems that postlarval food consumption was affected by the grazing activity of conspecifics despite an abundance of food.

Grazing would have increased the patchiness of food. Even when the densities were reduced by mortality in the high initial density treatments, the food would have been very patchy due to intensive previous grazing. Postlarvae entering recently grazed bare patches would have begun costly searching movements, whereas those encountering patches with a low diatom density would have consumed food at a slower rate. In both cases their growth would be reduced, and this form of exploitative competition, which essentially reduces access to food, would increase with density, and have persistent effects.

Effect of Density on Postlarval Survival

Density dependent mortality of postlarvae was found in both experiments, and has also been found in large-scale hatchery experiments, where food limitation at high density has been suggested as the underlying cause (Heasman et al. 2001, Daume et al. 2001, Daume et al. 2004). While food limitation may cause density dependent growth, our results suggest a different process causes the density dependent mortality.

Because alternative processes such as density-dependent predation (Shepherd & Daume 1996) or competition for space (McShane 1991) are absent in the hatchery, the density dependent mortality might be due to exploitation competition leading to either starvation, or a reduction in overall health that makes the postlarvae more susceptible to other agents of mortality. Density dependent mortality of this nature has been described for several species (Creese & Underwood 1982, Marshall & Keough 1994). One would expect such mortality to be delayed depending on the energetic reserves of the postlarvae at the start of the experiments, yet mortality in the high-density treatments actually occurs soon after the start of the experiments. It seems highly unlikely that starvation would take effect so quickly, and before differences in growth start to appear. In the first 2–3 wk after settlement, growth is minimally affected by the diatom composition because of the remaining yolk reserves (Daume et al. 2000, Roberts & Lapworth 2000) and the uptake of dissolved organic matter (Manahan & Jaekle 1992, Shilling et al. 1996), so that effects on mortality are unlikely until after this time.

Density dependent mortality would be expected to be less intense, or take longer to come into effect where the food is more abundant, because the food intake of the abalone would be substantially higher. In these experiments, mortality at high initial postlarval densities occurred at the same rate, irrespective of food level. In a large scale experiment in the hatchery (Daume et al. 2004) mortality was shown to be higher overall in the excess food treatment. This suggests that mortality is unrelated to starvation, and that some other mechanisms were at work.

Contact between individuals reduces growth in juvenile abalone, perhaps because of elevated levels of stress (Huchette et al. 2003a, Huchette et al. 2003b). At higher densities this would occur more often and might be a cause of the density-dependent mortality observed. Contacts between postlarvae however, did not seem to affect their behavior and are unlikely to cause the sharp declines in survival recorded.

Pathogens such as protists, viruses, or bacteria are well known agents of mortality in aquaculture (Bower 1987, Shepherd & Breen 1992). Although we have no direct evidence for any pathogen, higher rearing densities imply an increased contact between individuals and a higher probability that one or more individuals carry a pathogen. Increased contact between individuals or with mucus trails thus increased transmission of a pathogen at high densities, and may be the cause of the mortality that is observed here. Bower (1987) notes that smaller abalone (<1.5 mm) were far more susceptible to a pathogenic protist, so that these postlarvae may be highly vulnerable.

These density-dependent processes may simply be an additional pressure that increases the postlarvae's susceptibility to other stresses. These stresses could include aspects such as oxygen or carbon dioxide supersaturation or depletion in the diffusive boundary layer above the substratum (Searcy-Bernal 1996). This effect might account for the greater mortality that occurred after 2 wk in the excess food treatments of the second experiment. The diatoms were very abundant in these treatments by this time, so that the diurnal oxygen production, or nocturnal consumption, of the algae may have contributed to the mortality in the postlarvae. Because the contribution of the biomass of postlarvae to oxygen concentrations is not likely to be significant in comparison to diatoms, and diatoms were reduced by high larval densities, the boundary layer effect alone cannot explain the density-dependent mortality.

We tentatively conclude that the effect of density on mortality may be due to a pathogen, or a complex interaction between the factors discussed above.

Implications

When considering commercial systems these results must be interpreted with care, due to the small scale at which these experiments were conducted. Whereas small containers such as petri dishes and jars may not closely match conditions in hatcheries, their use has been widespread in abalone aquaculture research (Kawamura et al. 1998a, Roberts et al. 1999a, Roberts et al. 1999b). The fact that they can be easily manipulated makes them ideal for experiments aiming at identifying what is happening at a process level. Here, the existence of density dependent growth and mortality has been demonstrated in larger scale experiments (Heasman et al. 2001, Daume et al. 2001, Daume et al. 2004). Using small containers has allowed us to confirm that intraspecific competition for food is the cause of reduced growth at high density in postlarval *H. rubra*. Identifying that density-dependent mortality is not due to a shortage of food is also of enormous value.

From an abalone farm perspective, the efficiency of production is paramount. This often requires a balance to be found between the net biomass yield, the time taken to grow the abalone to market size and the cost of infrastructure and labor. Whereas density was shown to have a significant impact on the growth of postlarvae, food level was more important. Careful monitoring and the regular addition of supplemental diatoms would allow farms to grow postlarvae in high densities while maintaining reasonably high growth rates. The causes of density-dependent mortality have not been adequately identified, so that it is hard to say what management strategies would be most effective, but our results should encourage more work in this area. Commercial scale trials (Heasman et al. 2001, Daume et al. 2004) indicate that although survival rates are poorer, the number alive after 2 mo is still greater at high initial densities. Because production of large numbers of larvae is becoming easier, settlement of larvae at high densities may be the most efficient mode of production.

Although natural conditions are also different from those used here, it seems possible that the same density dependent mechanisms would operate on postlarvae in small patches of habitat, and these may play a role in regulating natural populations. This study highlights the importance of a process level understanding of the mechanisms underlying density-dependent growth and survival in abalone and opens up a range of new questions on these processes. Possible pathogens of postlarvae and the role of the boundary layer in the early life stages deserve further research.

NURSERY CULTURE OF THE ABALONE *HALIOTIS LAEVIGATA*: LARVAL SETTLEMENT AND JUVENILE PRODUCTION USING CULTURED ALGAE OR FORMULATED FEED

SABINE DAUME^{1,*} AND STEPHEN RYAN^{1,2}

¹Department of Fisheries, Research Division, PO Box 20, North Beach, WA 6920, Australia;

²cf- Great Southern Marine Hatcheries, PO Box L34, Little Grove, Albany WA 6330, Australia

ABSTRACT This study was conducted to investigate the settlement, growth, survival, and size variability of the abalone *Haliotis laevigata* on commercial scale. At settlement, two plate conditioning times for the green alga *Ulva lens* (conditioned for 6 or 8 wk) were evaluated and compared with plates colonized by different diatom species (*Navicula cf. jeffreysi* and *Cocconeis* sp.). In a choice experiment an overall settlement rate of 87% was estimated 3 days after larval release. The majority of the larvae chose to settle on *U. lens* (61% on 8-wk-old and 14% on 6-wk-old *U. lens*, with average algal cover of 97% and 82% respectively). Larvae showed a clear preference for older than for younger *U. lens*, with similar percentage cover, indicating that the developmental stage of the alga and not percentage cover per se is important in settlement induction. Only 7% and 5% respectively of the settled larvae were found on the plates colonized by the diatom species *N. cf. jeffreysi* and *Cocconeis* sp. Results clearly demonstrate that *U. lens* provides a suitable substrate to improve the settlement of *Haliotis laevigata* larvae on commercial scale. Juvenile growth ($\mu\text{m day}^{-1}$) on a mixed diet of *U. lens* and *N. cf. jeffreysi* was not constant and increased with size to 70–80 $\mu\text{m day}^{-1}$. Both growth rate and size variability increased over time until juveniles reached approximately 5 mm in shell length. The survival declined to ca. 30% at 44 days after settlement but stabilized thereafter. Distinct increases in size variability were observed between 3 and 16 and between 30 and 44 days after settlement, followed by elevated growth rates and a change from monomodal to multimodal distribution at day 44. The latter coincided with a shift in diet from a diatom-dominated diet to a macroalgal diet of *U. lens* at day 44. The increase in growth rate between 3 and 16 days is believed to reflect a shift in nutrition with postlarvae switching from absorbing yolk reserves to efficient exogenous feeding. The growth, survival, and size variability of juveniles was assessed when feeding on algal diets as well as a formulated diet. Juveniles grew faster on *U. lens* than on a formulated feed or plates colonized with the diatom *N. cf. jeffreysi*. Results indicate that growth of juveniles may be more variable when feeding on natural feed (*Navicula cf. jeffreysi*, *U. lens*) than on a formulated feed. However, until a feed is formulated that can match the mean growth rates achieved on *U. lens*, we suggest keeping juveniles on plates colonized with *U. lens* as long as possible. Juvenile *H. laevigata* should not be weaned onto formulated feed until they reach at least 5 mm in shell length.

INTRODUCTION

Australia has one of the world's largest abalone fisheries and its abalone aquaculture industry is expanding (Fleming 2000). With wild abalone fisheries declining in other countries, the interest in abalone aquaculture has increased substantially.

Since the inception of abalone aquaculture in Australia, research has focused on achieving the best growth rates possible in growout systems. This is because any increase in growth rates reduces production time and will usually have large cost benefits for an abalone farm. Recently it has been shown that differences in early growth of the abalone *Haliotis rubra* Leach persisted and were amplified by the end of a 4-mo growth trial (Daume et al. 2004), suggesting that early growth is important in determining later performance. Despite this result and the consequent benefits to the abalone aquaculturist, very little emphasis has been placed on improving growth rates of juvenile abalone.

Laboratory experiments have shown that the macroalgae *Ulva lens* Crouch is a suitable settlement inducer for larvae of the abalone *Haliotis rubra* Leach and *H. laevigata* Donovan (Daume et al. 2000). These findings were recently verified in the nursery for *H. rubra* (Daume et al. 2004). However, the growth rates of postlarvae (up to 3 mm in shell length) feeding on *U. lens* have been less promising and significantly better growth was achieved with benthic diatom species (Daume et al. 2000).

Formulated feeds have long been recognized to have beneficial effects for the growth and survival of juvenile abalone (Fleming et al. 1996). Experiments conducted in Australia showed that juve-

nile abalone can achieve maximum growth rates of up to 53 $\mu\text{m day}^{-1}$, and 90 $\mu\text{m day}^{-1}$ for animals ranging between 3 and 18 mm and 7 and 20 mm in shell lengths respectively when feeding on an unspecified formulated diet (Table 6 in Fleming et al. 1996). There are several studies on growth and survival of abalone juveniles when feeding on different algal species and growth rates of 60–100 $\mu\text{m day}^{-1}$ can be expected for juveniles at 3–4 mm in shell length (see review by Kawamura et al. 1998a). Some studies compared formulated diets to an algal diet. For example higher growth-rates were achieved with juvenile abalone (*H. fulgens*), of approximately 13 mm in shell length, feeding on a formulated diet compared with juveniles feeding on macroalgae (Viana et al. 1993). Corazani and Illanes (1998) showed a similar trend with larger abalone of *H. rufescens* (~21 mm in shell length). Knauer et al. (1996) found no significant difference in growth rates of *Haliotis midae* juveniles (3–11 mm in shell length) when comparing a diatom diet (50 $\mu\text{m day}^{-1}$) and a formulated diet (59 $\mu\text{m day}^{-1}$). However the species composition and density of diatom species was not given in this study. Results of these studies indicate that formulated diets may support similar or better growth in larger juveniles, however abalone farmers still have to rely on algae as a settlement inducer and as a food source for recently settled post-larvae. Significantly better growth rates on an algal diet are expected for postlarvae and young juveniles.

Growth in abalone is highly variable (Day & Fleming 1992). The patchiness of natural food on the settlement plates is likely to contribute to the large size variation of juveniles experienced in nurseries. Formulated feed may allow a more constant form of nutrition potentially resulting in less size variation at the end of the nursery phase. By using formulated feed, farmers would become

*Corresponding author. E-mail: sdaume@fish.wa.gov.au

independent from seasonal variation in food supply and reduce variation between sites, tanks, and even plates. Formulated feed would also provide a great advantage when algal food becomes limited at the later stages of the nursery phase when juvenile grazing pressure is very high.

In this study three experiments were conducted to investigate settlement as well as growth and survival during the early development of *Haliotis laevis* when feeding on algal as well as a formulated diet. The size variability of animals in all treatments was assessed over time to determine if juvenile populations feeding on formulated feed show less size variation.

Experiment 1: A large-scale settlement experiment was conducted to test the suitability of different algal species as settlement cues for *H. laevis* larvae in a commercial abalone nursery. At settlement, diatom films dominated by the cultured diatom *Navicula cf. jeffreyi* or *Cocconeis* sp. were compared with plates covered by the green alga *U. lens* at two different developmental stages (6 and 8 wk old). **Experiment 2:** Settlement, growth and survival were estimated on a mixed diet of cultured algae (*U. lens* and *Navicula cf. jeffreyi*). Previous work has shown that nursery plates seeded with *U. lens* result in high and consistent settlement, whereas the diatom *N. cf. jeffreyi* support rapid growth of young postlarvae (Daume et al. 2000, Daume et al. 2004). This experiment was conducted to investigate if regular inoculation at commercial scale with the diatom *N. cf. jeffreyi* can sustain rapid growth until juveniles reach ca. 4 mm in shell length. **Experiment 3:** The potential for a shorter algal-reliant nursery approach was investigated by weaning young juveniles (3.79 ± 0.06 mm in shell length) onto formulated feed 10 wk after settlement. This short-term approach was compared with the traditional long-term nursery system utilizing cultured algae. The natural food was provided separately to determine which of the algal diets *U. lens* or *N. cf. jeffreyi* achieves the better growth-rates in juveniles >3 mm in shell length.

METHODS

Location

Experiments were conducted at ambient temperature at a commercial abalone farm, Great Southern Marine Hatcheries (GSMH), Albany, Western Australia between November 2001 and June 2002. The farm provided the abalone larvae and the diatom inocula for the trials.

Experiment 1: Larval Settlement on Different Algal Species

Preparation of Tanks and Plates

Three semicommercial nursery tanks (490 L) were each set up with 3 baskets in series that each held 20 settlement plates (= 60 plates/tank). Airlines were installed on the tank bottom along each side and down the center of the line of baskets (3 airlines/tank). Four treatments were tested: 6- and 8-wk-old *U. lens* and the diatom species *Cocconeis* sp. and *Navicula cf. jeffreyi*, both cultured for 2–3 wk on the plates. Five plates of each treatment were alternated so that each tank received 15 plates of each treatment, thus providing 45 plates for each treatment in total.

Algal culture

***Ulvea lens* seeding:** To produce mass spore release, plates with large mature patches of *U. lens* and well-developed sporangia

were selected, wiped clean to remove any diatom film, and stored in 1- μ m filtered seawater under two layers of 70% shading cloth, 2 wk prior to starting the conditioning of the experimental plates. *U. lens* seed plates were then placed between the baskets of the experimental tanks (4 seed plates per 1000 L tank), while the tanks were maintained with no water flow, low aeration, and without shading. A complete f/2 mix, including silicates, was applied (40 g 1000 L⁻¹ Microalgae Food, Manutech, Port Lincoln, Australia). These methods for spore collection were adapted from Takahashi and Koganezawa (1988). The release of zoospores is triggered by the increase in water temperature, nutrients and light. The largest release occurred 4–5 days after the introduction of seed plates.

Diatom Culture and Inoculation

Cultures of *Navicula cf. jeffreyi* and *Cocconeis* sp. were established in horizontally laid algal bags progressively increased in size up to commercial size bags of ca. 1 \times 2 m. The diatom culture was harvested during the exponential growth phase (4–6 days after inoculation) and mixed into suspension. The diatom density was determined before tanks were inoculated. A 15 L inoculum (10^5 – 10^6 cells mL⁻¹) was used in each tank. A complete f/2 mix was applied (40 g 1000 L⁻¹). The tanks remained static with low aeration for 24 h and then received low water flow with light aeration for 2–3 days.

Diatom Cell Density and Percentage Cover of *Ulvea lens*

The number of diatom cells and the percentage cover of *U. lens* were estimated under an inverted compound microscope in 15 randomly chosen fields of view on three sub samples (2 \times 2 cm) of six plates per treatment at the time of settlement.

Larval Settlement

One hundred thousand larvae were released into each tank and left with very low water flow and low aeration for 3 days. Banjo sieves (118 μ m) were fitted onto each standpipe until settlement to prevent the escape of larvae. The settlement rates of larvae were estimated on six whole plates (30 \times 40 cm) per tank after 3 days. Plates were kept submerged in seawater during counts and replaced into tanks immediately after measurements. A grid with equal size squares was placed inside the tray and a stereomicroscope was mounted above the tray to count and assess the settled larvae.

Experiment 2: Settlement and Growth on a Combined Algal Diet (*Ulvea lens* and *Navicula cf. jeffreyi*)

Preparation of Tanks and Plates

The same tank set up was used as in the previous experiment. Three tanks with 60 plates each were conditioned with *U. lens* 7 days before larval settlement and then inoculated with 15 L of cultured *N. cf. jeffreyi* per tank, 4 days before settlement. The seawater was filtered to 1 μ m and provided with a flow rate of 5–7 L min⁻¹.

Larval Settlement

One hundred thousand larvae were released into each tank and left with very low water flow and low aeration for 3 days. The settlement rates of larvae were estimated on whole plates after 3 days (see earlier).

Algal Inoculation

Tanks were inoculated with 15 L of *Navicula cf. jeffreysi* culture, 4 days before and 30 days after larval settlement and every 2 wk thereafter until the end of the trial. The details of algal culture and inoculation are described earlier.

Diatom Cell Density and Percentage Cover of *U. lens*

The number of diatom cells and the percentage cover of *U. lens* were estimated in 12 randomly chosen fields of view of six plates per tank under an inverted compound microscope at $\times 200$ magnification.

Growth and Survival of Juveniles

Juveniles were reared on a combined diet of *U. lens* and diatoms until they reached approximately 3 mm in shell length. Counts and measurements of the abalone were undertaken under a dissection microscope on six plates per tank at approximately 2-wk intervals.

Experiment 3: Assessment of Different Nursery Approaches

Early Weaning Onto Formulated Feed Versus Algal Feed

After 10 wk, when juveniles reached an average of 3 mm in shell length in the preceding experiment, all animals were taken off the plates and randomly assigned to 3 different treatments. (1) A subsample of 7,500 animals were transferred into three experimental raceways (1 m \times 300 mm \times 30 mm) and stocked at a density of 2,500 animals each (70% cover). Abalone were weighed and gradually introduced to a commercial weaner diet over the next 2–3 days. Animals were fed to excess at 1% of their body weight every day for the duration of the experiment. (2) Three semi-commercial nursery tanks (see previous experiments) were set up with plates covered by *Ulvebella lens*. (3) Three additional nursery tanks were stocked with plates colonized by *Navicula cf. jeffreysi*. The abalone were placed onto one horizontal settlement plate on top of each basket and left for 24 h allowing them to redistribute across all feed plates. Animals reached a stocking density of ca. 50 animals per plates (ca. 3,000 per tank). All tanks and raceways had separate inlets and outlets. The seawater was filtered to 5 μ m and provided at a flow rate of 5–7 L per min⁻¹.

Algal Inoculation

Tanks were inoculated with 15 L of *Navicula cf. jeffreysi* culture, 2 wk before the experiment started and every 2 wk thereafter. The details of algal culture and inoculation are described above.

Diatom Cell Density and Percentage Cover of *Ulvebella Lens*

The number of diatom cells and the percentage cover of *U. lens* were estimated in 12 randomly chosen fields of view of six plates per tank under an inverted compound microscope at $\times 200$ magnification.

Proximate Composition of Juvenile Diets

Diatom samples (*Navicula cf. jeffreysi*) were harvested and washed onto preweight 47 mm fiberglass filter paper using 0.5 M ammonium formate to remove residual salts. Samples of *Ulvebella lens* were scraped of the settlement plates and washed with ammonium formate. All samples were then freeze-dried, reweighed and, together with samples of the formulated feed, forwarded to the State Chemistry Laboratory, Werribee, Victoria, for a proximate analysis of protein, carbohydrate, and fat content.

Growth and Survival of Juveniles

Growth-rates and survival of abalone were determined by measuring the size of 72 juveniles per tank and raceway as well as counting the number of juveniles per tank and raceway every 2 wk. At 10 wk, when the algal food supply became limiting, animals were taken off the old plates and moved onto a new set of plates with the same algal diet. The experiment was terminated after an additional 6 wk when animals reached 10 mm in shell length in one of the treatments.

Data Analysis

Statistical analyses were carried out using the STATISTICA computer packages. The assumptions of normality and homogeneity of variance of residuals and normal quartile plots were checked graphically for each data set using boxplots.

Daume et al. (1999) showed that the attractiveness of the substratum changes with the presence of recently settled conspecifics. Consequently, individual settlement choices are not independent, so that the numbers of larvae on the plates were analyzed using a paired *t*-test. Larvae started settling earlier on *U. lens* (old Ulvella-OU, young Ulvella-YU) than on the two diatom species (*Navicula cf. jeffreysi*, -N, *Cocconeis* sp., -C). Paired *t*-tests were performed on (1) the difference between OU and YU within each tank, (2) the difference between the average of the *Ulvebella* treatments (OU + YU/2) and N, and (3) the difference between the average of the *Ulvebella* treatments (OU + YU/2) and C. Total settlement rates per tank were analyzed using a 2-way ANOVA with tank and basket position as factors.

Abalone shell length measurements in the early weaning experiment were analyzed by repeated measure analyses of variance. Data at the end of the experiment was also analyzed using a 1-way ANOVA with Tukey HSD test. Relationships between the growth rates of the juveniles and the % cover of the feed species were explored with a simple regression analysis. Size-frequency distributions were drawn and compared over time and between treatments where appropriate using descriptive statistics (size range, mean, standard deviation [SD], and coefficient of variation [CV]). The shape of the distributions was compared with a Normal distribution using Shapiro-Wilks *W* tests (STATISTICA). Inter quartile differences IQD between the first and third quartile were used as a measure of spread of the size-frequency distributions.

RESULTS

Experiment 1: Larval Settlement on Different Algal Species

Larval Settlement

An overall settlement rate of 87% was estimated 3 days after larval release (Table 1). Sixty-one percent of the larvae chose to settle on the old *U. lens*, 14% on the young *U. lens*, 7% on the diatom species *Navicula cf. jeffreysi* and 5% on the diatom *Cocconeis* sp. We detected a high variation between tanks (ANOVA, *P*

TABLE 1.
Percentage settlement (\pm SE) of *Haliotis laevigata* after 3 days ($n = 3$).

Treatments	Old <i>U. lens</i>	Young <i>U. lens</i>	<i>Navicula</i> sp.	<i>Cocconeis</i> sp.	Σ
% Settlement	61 \pm 14	14 \pm 1	7 \pm 0.3	5 \pm 0.5	87

= 0.025) and within tanks (ANOVA, $P < 0.001$). Plates closest to the outlet had more settled larvae than plates closest to the inlet. Old and new *U. lens* were significantly different (paired $t = 4.64$, $df = 2$, $P = 0.043$). In addition, there was a significant difference between the combined *U. lens* treatments (OU + YU/2) and both diatom treatments, *N. cf. jeffreyi* ($t = 4.412$, $df = 2$, $P = 0.048$) and *Cocconeis* sp. ($t = 4.804$, $df = 2$, $P = 0.041$).

At the time of settlement, the estimated percentage cover of the old *U. lens* was 97% and 82% on young *U. lens*. A cell density of 4,978 cells cm^{-2} was estimated on plates in the *Cocconeis* sp. treatment and 150,000 cells cm^{-2} on plates with *N. cf. jeffreyi*.

Experiment 2: Settlement and Growth on a Combined Algal Diet (*Ulveella lens* and *Navicula cf. jeffreyi*)

Larval Settlement

A settlement rate of $30\% \pm 6.5$ was estimated 3 days after larvae release. There was no significant difference between tanks (ANOVA, $P = 0.47$) or within tanks ($P = 0.36$).

Ulveella Lens Cover and Diatom Density

Ulveella lens covered between 50% and 70% of the plates for most of the growing period but around 58 days after larval release the cover decreased substantially (Fig. 1). Tanks were first inoculated with the cultured diatom *Navicula cf. jeffreyi* 4 days before larval settlement. Inoculations were repeated 30 days after settlement and then every 14 days thereafter.

At the time of settlement *U. lens* covered approximately 55% of the plate area (Fig. 1). *Nitzschia* sp. was the dominant species in the diatom assemblage on the plates with an estimate of 10,489 cells cm^{-2} . This species developed naturally on the plates. The cultured diatom *N. cf. jeffreyi* slowly increased over time from 533 cells cm^{-2} at the time of settlement to ca. 36,000 cells cm^{-2} and was the dominant diatom species from day 44 until the end of the experiment.

Growth, Survival and Size Variability of Juveniles <4 Mm in Shell Length

The water temperature during this trial ranged between 17 °C and 24 °C; with an average of 20 °C. Juveniles growing on a mixed

diet of cultured algae (*Ulveella lens*, *Navicula cf. jeffreyi*) reached 3.9 mm in shell length 72 days after larval release (Table 2). The growth-rates during the first 3 days after larval release were low; averages of approximately $40\text{-}\mu\text{m day}^{-1}$ were achieved during the following 41 days and ca. $69\text{-}\mu\text{m day}^{-1}$ during the last 28 days of the experiment. Post-settlement survival was estimated at 46%. 16 days after larval release, decreasing to 29% at 44 days and to 27% at the end of the experiment. The size range of juveniles increased substantially over time (Fig. 2, Table 3). After 10 wk the size of juveniles ranged between 2 and 5.1 mm in shell length and was nearly twice as large as ca. 2 wk earlier and about 37 times larger than at 3 days after larval release (Table 3). The SD, CV, and IQD increased over time. A large increase in at least one of the above measures was observed between 3 and 16 days, 30 and 44 days, and between 58 and 72 days. The skewness of the size frequency distribution changed from negative to positive between 16 and 30 days and between 44 and 58 days.

Experiment 3: Assessment of Different Nursery Approaches

Early Weaning Onto Formulated Feed Versus Algal Feed

The average water temperature declined from 19 °C during the first 8 wk to 17 °C during the second half of the experiment (Table 4). Growth rates and survival rates were highest on *U. lens*. Juveniles feeding on *U. lens* reached 10 mm in shell length in <15 wk (Table 5). Juveniles feeding on the diatom *Navicula cf. jeffreyi* or the formulated feed only reached about 5 mm in shell length at the end of the experiment, resulting in a significant difference between the treatments (ANOVA, $P < 0.001$). Animals feeding on *U. lens* were significantly larger than the ones feeding on the diatom *N. cf. jeffreyi* (Tukey posthoc test, $P < 0.001$) and on the formulated feed (Tukey posthoc test, $P < 0.001$).

The size range of juveniles from all three treatments increased substantially over time (Fig. 3, Table 5). After 16 wk the size range of juveniles from all three treatments was highest and varied between 7.6 (formulated feed) and 8.1 mm (*N. cf. jeffreyi*) to 13.9 mm (*U. lens*). The CV ranged between 0.2 and 0.3 in all treatments and was highest in the population feeding on the diatom *N. cf. jeffreyi* after 4 wk. There was a significant difference in SD between the treatments throughout the experiment (ANOVA, $P = 0.049$). The SD was significantly lower among juveniles feeding on formulated feed than those feeding on *U. lens* at 4 wk (Tukey posthoc test, $P = 0.01$), 6 wk ($P = 0.02$), and 8 wk ($P = 0.002$) and higher among juveniles feeding on *U. lens* than in populations of the other two treatments at 10 wk (Tukey posthoc, $P < 0.05$), 12

wk (Tukey posthoc, $P < 0.001$), and 16 wk (Tukey posthoc, $P < 0.05$). The IQD was higher in the juvenile population feeding on *U. lens* than in the juvenile populations of the other two treatments at 12 wk (Tukey posthoc, $P < 0.001$) and 16 wk ($P < 0.05$). However, when the mean size of the populations was taken into account, the IQD/mean was highest in the *N. cf. jeffreyi* treatment.

Ulvela Lens Cover and Diatom Density

At the start of the early weaning trial, *U. lens* covered about 55% of the plate area. The cover decreased continuously until only 11% of the plates were covered after 9 wk (Table 6). The cell density on the plates in the *Navicula cf. jeffreyi* treatment followed a similar trend. New plates were introduced at 10 wk with a higher % cover in the *U. lens* treatment and higher cell densities in the *N. cf. jeffreyi* treatment than at the start of the trial. *U. lens* cover and *N. cf. jeffreyi* cell density declined rapidly.

Proximate Composition of Juvenile Diets

Protein was highest in *U. lens* and lowest in samples from the diatom *Navicula cf. jeffreyi* (Table 7). All diets contained similar amounts of fat and ranged from 4% to 7%. The formulated diet was high in carbohydrates compared with other diets.

DISCUSSION

Settlement, Growth, Survival, and Size Variability

The findings of the first experiment clearly demonstrate that the green alga *Ulvela lens* provides a suitable substrate to improve the

settlement of *Haliotis laevigata* larvae on a commercial scale. Settlement was significantly higher in both *U. lens* treatments when compared with the diatom treatments, indicating that *U. lens* is more suitable to induce settlement of *H. laevigata* larvae than a monospecific diatom film. It also indicates that larvae can distinguish between different developmental stages of *U. lens*. Similar to these findings, the settlement of *H. rubra* larvae was higher on older compared with younger *U. lens* (Daume et al. 2001). In contrast to the previous study, *U. lens* covered the settlement plates almost completely in both treatments of experiment 1 (97% and 82% for old and young *U. lens* respectively), indicating that the developmental stage of the alga (such as the development of sporangia) may be more important for the settlement induction than the percentage cover *per se*.

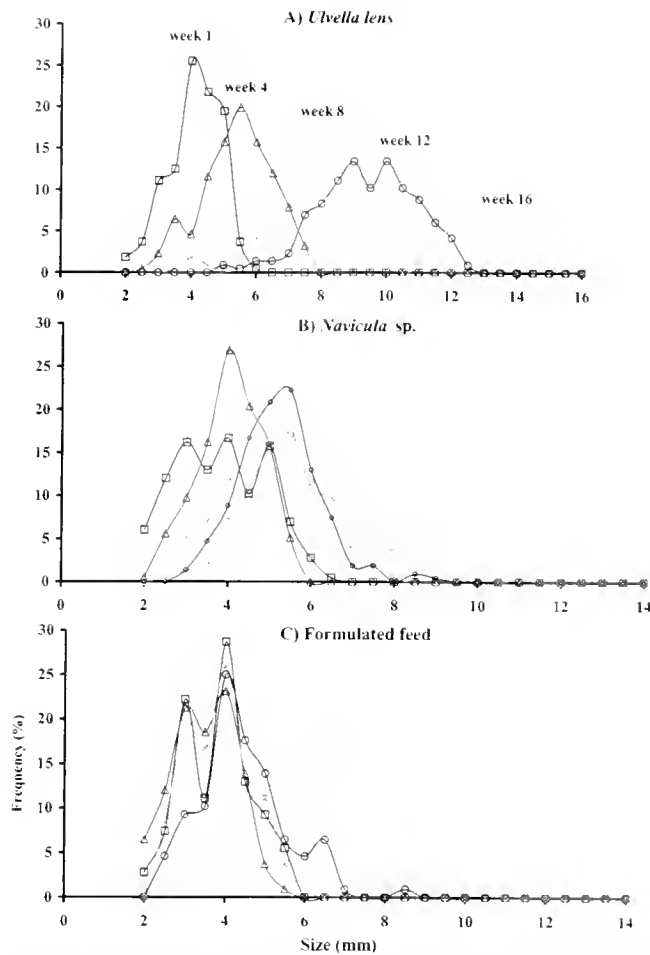

Figure 3. Size-frequency distribution of juveniles feeding on (A) *Ulvella lens*, (B) *Navicula cf. jeffreyi*, and (C) formulated feed after 1, 4, 8, 12, and 16 wk (Experiment 3).

About 30 days after the initial inoculation with the cultured diatom *Navicula cf. jeffreyi* this species out-competed the naturally developing diatom species *Nitzschia* sp., which dominated at the start of the experiment. This demonstrates that the species composition of a biofilm can be altered by inoculation of a cultured diatom. However, if competitive species are present at the time of inoculation, this process might take some time.

In this study, growth rates of $40 \mu\text{m day}^{-1}$ were recorded on a

combined diet of *U. lens* and *N. cf. jeffreyi* until juveniles reached 2 mm in shell length and $70 \mu\text{m day}^{-1}$ until juveniles reached 4 mm in shell length, which compares favorably to other studies reviewed in Kawamura et al. (1998). Although diatoms are a good food source for young post larvae (Daume et al. 2000), *U. lens* may prove to be just as nutritious as diatoms; however smaller juveniles may not be able to graze on it until they reach a certain size. In this study we provide some evidence that juveniles of 2–3 mm in shell length (between 44 and 58 days after larval release) are able to actively remove *U. lens* from the plates and access it as a food source. This was evident by a sharp decline in percentage cover of *U. lens* between these two measurements points. The cell density of the cultured diatom *N. cf. jeffreyi* was low at the start of the experiment, which may have contributed to the lower growth-rate of the abalone at this stage. However, it is more likely that higher growth-rates are observed towards the end of the trial because juveniles are able to access *U. lens* as a food source. As abalone grow, not only does their ability to access food change usually in accordance to their mouth size (Fleming et al. 1996), but also the apparent efficiency of the animal's radula. The radula undergoes morphologic changes during the animal's development and these changes may be linked to a shift in feeding habits from microalgae to macroalgae (Kawamura et al. 2001). The teeth may function as scoops when postlarvae are less than 1 mm in shell length whereas postlarvae larger than 1 mm may be able to scrape and feed on larger particles (Roberts et al. 1999a).

During the juvenile phase, growth of wild *H. laevigata* has been found to be linear (Shepherd 1988) and size variability should remain constant. However, at 44 days after larval release, we observed a clear shift in diet, which caused an increase in growth of the larger juveniles. This resulted in a greater variability (SD) and larger spread (IQD), and change from a uni-modal to a multimodal distribution. Another distinctive increase in SD and IQD was observed between 3 and 16 days after larval release, which coincides with an increase in growth-rate. This is believed to be a shift in nutrition from absorption of yolk reserves to efficient exogenous feeding (Kawamura et al. 1998a). The change in skewness from a longer left tail to a longer right tail after 16 and 44 days indicates that larger juveniles were growing faster. After day 44 the survival stabilized, suggesting that potential stresses associated with morphologic, physiologic, and nutritional changes were overcome.

Early Weaning onto Formulated Feed Versus Algal Feed

Several factors need to be considered when comparing the growth and the survival of juvenile abalone feeding on different food items; the food abundance and availability (e.g., patchiness of the food provided, the effort needed to remove a food item, and biomass ingested per unit grazing effort), and the digestibility and the nutritional value of the food item.

In this study all food was offered in excess but the cell density of *N. cf. jeffreyi* was low at times. Other studies have acknowl-

edged the difficulty to maintain high cell densities in the presence of heavily grazing juveniles (Kawamura et al. 1998b, Roberts et al. 1999b) and the results of this study support their findings. Thus the full potential of diatoms as a food source for juvenile abalone might have been underestimated in this experiment. However, the growth-rates of juveniles were very low despite the high cell density of *N. cf. jeffreyi* at the start of the experiment and when new plates were introduced. In contrast, post larvae 0.4–3.3 mm in shell length show superior growth when feeding on diatom species such as *Navicula* spp. when compared with *U. lens* (Daume et al. 2000). This indicates that diatoms are suitable for small juveniles but *N. cf. jeffreyi* is not sufficient to maintain adequate growth for juveniles larger than 3 mm in shell length. In comparison to the other diets *U. lens* had a relatively high protein content. This could have contributed to the better growth on this diet. Brown & Jeffrey (1995) reported a slightly higher protein concentration, higher fat content, and lower carbohydrate content in *Navicula jeffreyi* compared to the proximate composition of this study. However, it is well known that the biochemical composition of an algal species can change depending on culture conditions such as light intensity and nutrients (Thompson et al. 1993, Fábregas et al. 1996). In our study samples were harvested from the nursery and thus growing conditions were dependent on abalone culture conditions in the outdoor nursery environment that is certainly different from the culture condition in a controlled culture room.

The decline in growth rates, after juveniles were transferred onto new plates, indicates that juveniles might have been stressed and feeding might have slowed due to the handling. However, feeding must have been substantial because there was a subsequent rapid decline in *U. lens* cover and diatom cell density. It may be beneficial to introduce new plates, with the desired algae present, allowing juveniles to move onto the new plates to prevent handling stress. Animals on formulated feed were not transferred at this stage and growth-rates rose slowly.

Growth-rates of juveniles feeding on formulated feed were even lower than on the *N. cf. jeffreyi* at the start and slightly better at the end of the experiment but still remarkably lower than

growth-rates of juveniles feeding on *U. lens*. The growth-rates of juveniles feeding on formulated feed improved towards the end of the trial indicating that the feed may be suitable for juveniles larger than 4 mm in shell length. The formulated feed used in this experiment may not be well matched for the nutritional requirements of small juveniles. The formulated diet was lower in protein and higher in carbohydrates than *U. lens*. Unless a suitable formulated feed is found, which can match growth-rates achieved with the macroalga *U. lens*, we suggest keeping animals on plates colonized by *U. lens* as long as possible. However, the size variability was particularly high in the juvenile population fed on *N. cf. jeffreyi* followed by *U. lens* towards the end of the 16-wk experiment. In this study we provided initial evidence that juveniles feeding on natural food showed higher size variability than juveniles feeding on formulated feed. Feeding formulated diets instead of natural diets such as *N. cf. jeffreyi* may provide a more uniform supply of nutrition throughout the nursery phase (independent of season), growing conditions, and size of the animals; and may ultimately lead to higher growth rates and lower mortality and size variability if the food can be improved. However, culturing *U. lens* as a food source may prove to be more cost effective because there is only a small cost involved in culture set-up and fertilizer. In addition, once *U. lens* is in the nursery system it regenerates *in situ* and no costly algal culture is required. At the present stage we regard *U. lens* as the preferred food species for juveniles >3 mm in shell length, because of the ease with which *U. lens* can be cultured in the nursery and superior growth achieved on this alga.

ACKNOWLEDGMENTS

The authors thank the staff for providing the infrastructure, the abalone larvae, and diatom cultures to inoculate the tanks. They also thank Dr. Rob Day for providing statistical advice and Dr. Greg Maguire and Andrew Hancock for useful comments to improve the manuscript. Great Southern Marine Hatcheries in Albany Western Australia, hosted this experiment. Fisheries Research and Development Corporation supported this study as part of a larger program (FRDC 98/306).

UTILIZATION OF DIETARY PROTEIN, LIPID, AND CARBOHYDRATE BY ABALONE *HALIOTIS DISCUS HANNAI*: A REVIEW

SANG-MIN LEE

Faculty of Marine Bioscience and Technology, Kangnung National University,
Gangneung 210-702, Korea

ABSTRACT Feeding *Haliotis discus hannai* depends mainly on the use of macroalgae such as *Undaria* sp. or *Laminaria* sp., although the species is an important mariculture shellfish in Korea. Research on the utilization of protein, lipid, and carbohydrate in formulated diets by *H. discus hannai* has been conducted, and the results have been reviewed. *H. discus hannai* fed a formulated diet showed better growth performance than those fed a macroalgae based-diet. Casein, fish meal, soybean meal, cottonseed meal, and wheat germ meal are all good sources of dietary protein for *H. discus hannai*. The optimum dietary lipid content for *H. discus hannai* is from 2% to 5%. Marine fish oil, for instance squid liver oil, is a good dietary lipid source for *H. discus hannai*. Oil supplementation in diets is not necessary when fish meal as main protein source is used for *H. discus hannai* diets. Comparative growth rates were observed when *H. discus hannai* were fed diets containing each of the following carbohydrate sources: wheat flour, dextrin, sucrose, potato starch, or as a mixture combined with practical ingredients such as soybean meal, corn gluten meal, cotton seed meal, and wheat flour. These results may be used in developing practical feed formulation and improving aquaculture production of abalone.

KEY WORDS: *Haliotis discus hannai*, formulated diet, protein, lipid, carbohydrate

INTRODUCTION

Haliotis discus hannai is a commercially important shellfish species in Asia, especially, in Korea, China, and Japan. This species has several desirable characteristics for aquaculture including tolerance to low water temperatures, establishment of seedling production, and ability to withstand high stocking density (Kikuchi & Uki 1974, Uki & Kikuchi 1982, Kim et al. 1998). Farming of *H. discus hannai* in Korea has been developed since 1970, and aquaculture production is currently increasing at a rapid rate. It is likely to maintain this increasing trend in the production because of the decrease in wild abalone captures due to overexploitation, water pollution, and other causes. In culturing *H. discus hannai*, juvenile abalone are reared on diatoms cultured on plates until they grow up to about 5-mm shell length and then weaned on to marine macroalgae.

Abalone has a slow and very heterogeneous growth rate. The growth rate of *H. discus hannai* is approximately 1–2 cm in shell length per year depending on environmental conditions such as water temperature and food. The economic success of abalone aquaculture depends in part on the abalone growth during culture. Nutritional quality of feed is critical, among many factors affecting growth and survival of animals. In the wild, *H. discus hannai* eat mainly macroalgae, such as *Undaria* and *Laminaria*, which are predominated in Korea. It would be expensive to maintain or to culture an adequate supply of live algae. Lee et al. (1997) investigated the effects of experimental formulated diets, commercial diets, and *Undaria* (12.8% crude protein, 1.0% crude lipid) on growth and body composition of *H. discus hannai*. Experimental diets were formulated to contain 34.1% crude protein and 7.5% crude lipid. The abalone fed the experimental formulated diet and several commercial diets showed better survival and growth rate (Fig. 1) than those fed *Undaria*. Similar results for *H. discus hannai* and *H. fulgens* have also been observed in other studies (Nie et al. 1986, Viana et al. 1993). For further expansion of abalone farming, use of formulated artificial feeds is desirable to ensure a better growth.

Development of nutritionally balanced and cost-effective feeds is dependent on information on the nutritional requirements and feed utilization of the species. To date, nutrition research on *H. discus hannai* has identified dietary requirements of protein (Uki et al. 1986a, Mai et al. 1995a), lipids, and essential fatty acids (Uki et al. 1986b, Mai et al. 1995b, Mai et al. 1996), vitamins (Tan & Mai 2001), and minerals (Tan et al. 2001) for normal growth. Other studies have also been conducted to investigate the utilization of dietary sources for protein (Uki et al. 1985, Lee et al. 1998a, Lee et al. 1999a), lipid (Lee & Park 1998), carbohydrate (Lee et al. 1998b), and additives (Lee et al. 1998c, Lee et al. 1999b, Lee et al. 2000, Lim & Lee 2003) in the same species. Based on the nutritional information available, practical feed formulation (Lee 1998) has been studied to improve aquaculture production of *H. discus hannai*. The results of the research on the utilization of dietary protein, lipid, and carbohydrate in *H. discus hannai* are reviewed in this study.

PROTEIN

In nutritional studies on the animals, determination of their dietary protein requirement is generally considered as a primary step. Proteins are not only the major constituent of animal's bodies, but also function as enzymes and hormones. Therefore, a continuous supply of proteins with balanced amino acids is required for maintenance and growth of target animal. Without satisfying the protein requirement, adequate growth and health of the animal cannot be ensured. On the other hand, if excessive proteins are provided, some of them are metabolized as energy; thus the most expensive dietary component will not be effectively used. In the study conducted by Uki et al. (1986a) and Mai et al. (1995a) to determine the protein requirements of *H. discus hannai*, diets containing casein or fish meal as the protein sources were fed to abalone initially weighing 3.5 g and 0.4 g, for 40 days and 100 days, respectively. The research conducted by Uki et al. (1986a) showed that growth of *H. discus hannai* fed diets containing 20% to 30% crude protein was better. Mai et al. (1995a) estimated that the optimum crude protein level for growth of *H. discus hannai* was between 25% to 37%. Taylor (1992) and Coote et al. (2000) reported that dietary crude protein requirements of *H. kantschati-*

Figure 1. Weight gain [(final weight-initial weight) \times 100/initial weight] of *Haliotis discus hannai* fed the experimental diet, commercial diets and *Undaria* for 17 wk (data from Lee et al. 1997).

kana and *H. laevigata* were 30% and 27%, respectively. *H. midae* exhibited optimum growth rate when crude protein levels are 36% to 47% in the diets (Britz 1996, Sales et al. 2003). These optimum dietary protein levels for abalone are lower than those for most carnivorous and omnivorous fish and similar to those for several herbivorous fresh water fish, such as common carp and Nile tilapia (NRC, 1993). The reason for the different crude protein requirement between studies, even though the same abalone species were used and the rough requirement ranges reported as compared with other fish, is not clear but may be due to differences in abalone size, feeding trial periods, digestible protein to energy ratios, essential amino acid pattern in the diets, culture surroundings, or statistical analysis methods used in the studies. Differences in leaching rates of nutrients from the diets into water could also have resulted in the differences between the protein requirement studies.

Besides biologic protein requirements, economics, and culture strategy need to be considered in formulating practical feeds. This seems to be of primary importance for abalone farmers who want to grow their abalone to marketable size. In this respect, recent experience suggests that it might be necessary to include more than 20% crude protein in the formulation of the practical feeds for *H. discus hannai* to obtain good growth (Lee et al. 1998a). Furthermore, the dietary protein level should be higher to compensate essential amino acid imbalance (NRC 1993, Sales & Britz 2001) when high quality protein in diets is replaced by protein from byproducts without fine tuning of amino acid balance and poor digestibility of those substitutes. The formulation of artificial diets should be based on the availability of the nutrients in the ingredients used and the animal's requirements for those nutrients. Among dietary ingredients, the protein source is important, because protein is much more expensive than lipid or carbohydrate, and the growth of animal could be more influenced by availability of dietary protein sources. Thus, high-quality proteins are necessary for a good artificial feed for abalone. Uki et al. (1985) reported that casein was the best protein source for use in *H. discus hannai* diets. In addition, results conducted by Viana et al. (1993) showed that each of casein and fish meal was equally good protein source for growth of *H. fulgens*. Britz (1996) reported that low-temperature-processed fish meal and *Spirulina* were the most suitable candidates for primary protein sources in formulated diets for *H. midae*. These protein sources are expensive to use in the practical feeds, thus partial or total replacement of casein or fish meal by low-cost practical alternate protein sources would be promising for the economic advantage. An 18-wk growth trial was conducted by Lee et al. (1998a) to evaluate the practical dietary protein

sources for juvenile *H. discus hannai*. Three replicate groups of *H. discus hannai* averaging 110 ± 7 mg were fed one of ten diets containing casein, white fish meal (WFM), meat meal (MM), feather meal (FM), blood meal (BM), soybean meal (SM), corn gluten meal (CGM), cotton seed meal (CSM), *Undaria* powder (UP), or wheat flour (WF) as a dietary protein source. In addition, growth of abalone fed these dietary protein sources was compared with abalone fed macroalgae such as *Undaria* or *Laminaria*. Weight gain (Fig. 2) of *H. discus hannai* fed the diets containing casein, WFM, SM, CSM, or UP was significantly higher than those of abalone fed the other diets. The weight gain of abalone fed the FM, BM, CGM, or macroalgae diets was significantly lower than that of abalone fed the other diets. Lee et al. (1999a) also investigated the utilization of wheat germ meal (WGM) as a protein source replacing fish meal and soybean meal in formulated diet for juvenile *H. discus hannai*. Survival, weight gain, and shell growth of the abalone fed the diets containing 10% to 30% WGM were not different to those of abalone fed the control diet. It is concluded that WFM, SM, CSM, UP, and WGM can be used as good sources of protein in formulated diet for *H. discus hannai*.

It was suggested that a diet containing plant protein sources in combination with animal protein sources produced a better growth of abalone (*H. fulgens* and *H. asinina*) compared with diets containing plant protein sources alone (Guzman & Viana 1998, Bautista-Teruel et al. 2003). The good growth of abalone fed diets containing combination of plant and animal protein sources could have partly been attributed to the fact that some limiting essential amino acids in plant protein sources might be compensated by animal protein sources. Lee (1998) and Kim et al. (1998) also reported the efficiency of the use of combination of plant and animal protein sources in the practical diets for *H. discus hannai*.

LIPID

Dietary lipids play important roles in providing energy, essential fatty acid (EFA), and fat-soluble nutrients for normal growth of animal. Carnivorous fish have limited ability to use carbohydrates as an energy source, but can efficiently use dietary lipid as high as 10% to 25%. In comparison, almost all the herbivorous fish in-

Figure 2. Weight gain [(final weight-initial weight) \times 100/initial weight] of *Haliotis discus hannai* fed the diets containing various protein sources and macroalgae (*Undaria* and *Laminaria*) for 17 wk. Data with different letters were reported as significantly different using ANOVA and a multiple range test with $P < 0.05$ (data from Lee et al. 1998a).

Figure 3. Weight gain [(final weight-initial weight) \times 100/initial weight] of *Haliotis discus hannai* fed the diets containing various lipid sources for 20 wk. Data with different letters were reported as significantly different using ANOVA and a multiple range test with $P < 0.05$ (data from Lee & Park 1998).

cluding abalone can efficiently use carbohydrates as an energy source, but cannot use high lipid levels (Lee et al. 1998b). Mai et al. (1995b) reported an optimum lipid requirement in a formulated diet for *H. discus hannai* to be about 3% to 7%.

EFA requirements in fish differ among species (NRC 1993). Fresh water fish require 18:3n-3 and/or 18:2n-6, whereas marine fish require n-3 highly unsaturated fatty acids (n-3HUFA) such as EPA and DHA. The EFA requirement of *H. discus hannai* has been studied by Uki et al. (1986b). The study showed that *H. discus hannai* requires n-3 and n-6 HUFA as EFA, and the n-3HUFA requirement was about 1% in a diet containing 5% lipid. Experiments were carried out by Lee and Park (1998) to evaluate the effects of lipid source in formulated diets on the growth and body composition of juvenile *H. discus hannai*. Three replicate groups of *H. discus hannai* averaging 151 ± 5 mg were fed the casein-based diets containing 5% squid liver oil (SO), 5% corn oil (CO), 5% beef tallow (BT), 2.5% SO + 2.5% CO, and 2.5% SO + 2.5% BT for 20 wk. Weight gain (Fig. 3) and shell growth of *H. discus hannai* fed the diets containing SO, SO + CO or SO + BT were significantly higher than those of abalone fed the diets containing CO or BT alone. These data indicate that SO is a good dietary lipid source for juvenile *H. discus hannai*. Oil supplement in diets is not necessary when fish meal is used as the main protein source (Lee & Park 1998). Considering the results (Uki et al. 1986b, Mai et al. 1995b, Lee & Park 1998), 2% to 5% crude lipid may be recommended for practical *H. discus hannai* diets, when EFA requirement is satisfied with marine fish oils rich in n-3HUFA.

CARBOHYDRATE

Feed costs in aquaculture can be minimized by optimal use of low-cost energy sources such as carbohydrates. The ability of fish to use different carbohydrate sources and levels differs among species (Wilson, 1994). The utilization of dietary carbohydrates in aquatic animals seems to be related to their digestive and meta-

Figure 4. Weight gain [(final weight-initial weight) \times 100/initial weight] of *Haliotis discus hannai* fed the diets containing various carbohydrate sources and macroalgae (*Undaria* and *Laminaria*) for 20 wk. Data with different letters were reported as significantly different using ANOVA and a multiple range test with $P < 0.05$ (data from Lee et al. 1998b).

bolic systems adapted to different aquatic environments and to dietary carbohydrate level and complexity (Walton & Cowey 1982). Carbohydrate utilization by most carnivorous fish is lower than that of herbivorous and omnivorous fish. The growth of fish is reduced when fed carbohydrate-deficient diets because other nutrients such as protein are catabolized for energy and to provide metabolic intermediates for the synthesis of other biologically important compounds (Wilson 1994). A 20-wk growth trial was conducted by Lee et al. (1998b) to investigate the utilization of carbohydrate sources by juvenile *H. discus hannai*. Four replicate groups of *H. discus hannai* averaging 125 ± 1.1 mg were fed one of eight diets containing 24.2% wheat flour (WF), 20% dextrin (DEX), 20% sucrose (SUC), 10% α -potato starch + 10% β -potato starch (ab-S), 15% α -potato starch (a-S15), 20% α -potato starch (a-S20), 25% α -potato starch (a-S25), or mixture of carbohydrates (MIX) with practical ingredients such as soybean meal, corn gluten meal, cotton seed meal, and wheat flour. These formulated diets were compared against *Undaria* or *Laminaria*. Survival, weight gain (Fig. 4) and shell growth of *H. discus hannai* were not significantly affected by the different dietary carbohydrate sources, although those fed the a-S15 diet had slightly lower weight gain than those fed the other formulated diets. *H. discus hannai* fed *Laminaria* had the lowest weight gain, followed by those fed the *Undaria*. These data indicate that *H. discus hannai* were able to efficiently use the carbohydrate sources used in the study. The lower growth rate of *H. discus hannai* fed the a-S15 diet may be due to its high lipid content (7.5%) compared with those (3.1% to 5.3%) of other diets. Research on the digestive enzymes of *Haliotis* spp. has shown that abalone have high protease, amylase, cellulase, and alginase, but low lipases (Oshima 1931, McLean 1970, Cho et al. 1983, Nakagawa & Nagayama 1988, Gomez-Pinchetti & Garcia-Reina 1993, Britz et al. 1994). These investigations indicate that *H. discus hannai* use carbohydrate more efficiently than lipids as an energy source.

ABSTRACT Histologically, the epithelium of the digestive tract is pseudostratified columnar type, which is composed of 3 kinds of cells (i.e., granulated cells, nongranulated cells, and mucus cells). The subsets of these three types of cells vary from region to region. By an enzyme-histochemical method, leucine aminopeptidase reactivity was localized principally within the cytoplasm of granulated cells in the buccal cavity, esophagus, esophageal pouch, hepatopancreas, and the third intestinal region, which implies that these sites are responsible for the synthesis and secretion of this peptidase for the digestion of proteinaceous nutrients.

KEY WORDS: *Haliotis asinina*, abalone, digestive tract, aminopeptidase

INTRODUCTION

The abalone *Haliotis asinina* is considered the most economically important abalone among the three species found along the coastal water of Thailand (Nateewathana & Bussawarit 1988) because of its good taste, high proportion of flesh, and the fastest growth rate. Due to increased demand, the collection of these abalone from natural habitat could not keep pace. To increase the abalone stocks and yields, the animals have been cultured and fed artificial diets for enhancing the growth rate (Serviere-Zaragoza et al. 1997). The rate of growth and nutritional composition of abalone were significantly affected by the level of proteins in the diet (Britz & Hecht 1997), which could be increased up to 30% (Fallu 1991). This high protein content could be broken down by proteolytic enzymes in the digestive tract of abalone, even though abalone are considered to be herbivorous animals that feed on mainly macroalgae, which are richer in carbohydrates. One possible protease inducible in the abalone is aminopeptidase, which is a family of zinc-dependent enzyme that catalyzes the hydrolysis of amino acid residues at the amino terminus of peptide substrates (Acosta et al. 1998). The source of this enzyme is most likely the epithelium of the digestive tract. The epithelial cells of the digestive tract of gastropods have been classified into 3 cell types and termed by different names; for example, columnar storage cell, secretory cell and mucus-producing cell (Tiebskorn & Kunast 1990), nonciliated, ciliated, and glandular cell (Leal-Zanchet 1998, Roldan & Garcia-Corrales 1988), Campbell (1965) and Chitramvong et al. (2000) have studied the abalone and also classified these epithelial cells into 3 types, which include pigmented cell, secretory cell, and mucus cell. The aim of this study is to investigate the presence of aminopeptidase in epithelial cells of some parts of the digestive tract of *H. asinina* by an enzyme-histochemical method.

MATERIALS AND METHODS

Collection of Abalone Specimens

Adult abalone *H. asinina* (age >16 mo old) of both sexes were obtained from the Coastal Aquaculture Development Center, De-

partment of Fisheries, Prachuabkirikan province, Thailand. The animals were reared in the raceways of concrete tanks, which were well flushed with mechanically circulated seawater and air delivery system to maintain controlled environment. Abalone were fed with a diet of macroalgae (*Gracilaria* spp. and *Laminaria* spp.) supplemented with artificial food, and kept under normal daylight cycle.

Burstone and Folk Method for Detecting Aminopeptidase

Abalone with body weights of 36.5 ± 2 g were anesthetized with 5% magnesium chloride for about 30 min. The shells (average size of 6.5 cm × 2.8 cm) were removed and digestive organs were dissected out and diced into small pieces before being embedded in the cryo-supporting medium. Frozen specimens were sectioned at 5- μ m thick. The cryosections were fixed in two changes of chloroform for 4 min each, then hydrated in graded series of acetone, and finally in distilled water. The sections were incubated in a substrate solution containing the mixture of L-leucyl-L-naphthylamide, distilled water, tris buffer and garnet GBC for 1h at 37°C, then in tap water for 5 min and counterstained by Hematoxylin. After the final run through tap water for 10 min, the sections were mounted on glass slides in buffered glycerol (Burstone & Folk 1956).

Histology of the Digestive Tract

To identify the cell types and characterize the cellular details for the enzyme localization, the histology of the abalone digestive tract was also studied from paraffin and semi thin plastic sections by preparing the specimens as follows.

For paraffin sections, various parts of the digestive tract were cut and fixed in the fixative of Bouin at 4 C overnight. Specimens were washed in 70% ethyl alcohol for removal of the fixative. Then, they were dehydrated through a graded series of ethyl alcohol (70% to 100%) for 1–2 h each, cleared with dioxane, infiltrated and embedded in paraffin wax, sectioned at 5 μ m thick, and finally stained with Hematoxylin-Eosin (H&E) or Hematoxylin-PAS (H&PAS). The specimens were observed and evaluated for the characteristics of each cell type under microscope equipped with a digital camera.

For semithin plastic sections, the corresponding parts of the digestive tract were fixed in a solution of 4% glutaraldehyde and

*Corresponding author. Fax: +662-354-7168; E-mail: sepso@mahidol.ac.th

2% paraformaldehyde in 0.1 M Millonig buffer at 4°C overnight. After washing with buffer, the samples were postfixed in 1% osmium tetroxide in 0.1 M Millonig buffer at 4°C for 1 h, and then dehydrated in graded series of ethanol and pure propylene oxide. After that the specimens were infiltrated and embedded in Araldite 502 resin, and finally polymerized at 60°C for 24 h. Blocks of plastic embedded specimens were sectioned at 1 µm. These semithin sections were stained with 1% methylene blue, and then observed under microscope equipped with a digital camera.

RESULTS

Histology and Aminopeptidase Reactivity

The Buccal Cavity

The epithelium of buccal cavity consists of 3 cell types, the tall granulated columnar cells bearing microvilli; which appear as a "brush border" under the light microscope, the nongranulated cells, and the mucus cells having a "goblet" appearance; which are widely scattered in the epithelium (Fig. 1a). The granulated cells show red orange product in the apical cytoplasm overlapping on the granulated area (Fig. 1c), indicating the presence of aminopeptidase in this area of the cytoplasm, and at the luminal surface, whereas nongranulated and mucus cells are not stained. The control section does not show the presence of aminopeptidase (Fig. 1b).

The Esophagus

The epithelium of the esophagus contains 4 cell types: 2 types of granulated columnar cells, nongranulated columnar cells, and mucus cells (Fig. 1d to f). The two types of granulated columnar cells are distinguished by the presence of different size granules and color (i.e., in H&E stain type 1 contains small brownish granules whereas type 2 contains large reddish eosinophilic granules, whereas in semithin section all the granules appear bluish with different intensities (Fig. 1d to f)). The granulated cells with large reddish granules, nongranulated cells, and the mucus cells do not show aminopeptidase reactivity, whereas the granulated cells with small brownish granules show intense aminopeptidase reactivity in the granules (Fig. 1h). The control section does not show red product (Fig. 1g).

The Crop

The epithelium of crop appears to be pseudostratified columnar epithelium that is composed of only one-cell type (i.e., the tall columnar cells, bearing a brush border). These cells also contain small clear mucin granules that are tightly packed together in both the apical and basal cytoplasm (Fig. 1i). This cell type shows only weak reactivity at its luminal surface but not in the cytoplasm (Fig. 1k), hence probably does not contain aminopeptidase enzyme.

The Stomach

The stomach epithelium comprises 3 cell types: mucus cell, tall granulated columnar cells with fine granules in the apical cytoplasm, and nongranulated columnar cells. The epithelium is covered by a thick layer of PAS-positive gastric shield (Fig. 1l). The intense aminopeptidase reactivity is present in the gastric shield overlying the epithelium but absent in the epithelial cells' cyto-

plasm. (Fig. 1n). The control section shows negative reaction (Fig. 1m).

The Intestine

The intestinal epithelium contains four types of columnar epithelial cells. The former group comprises two types of granulated cells with different characteristics of granules (i.e., the first type of granulated cell appears to be similar to those found in the stomach whereas the second type possesses larger granules with varying density (Fig. 2a, b, c)). There is one type of nongranulated cell (Fig. 2b), and one type of mucus cell appearing similar to those in the crop (Fig. 2a). All two types of granulated cells show intense aminopeptidase reactivity in their cytoplasm (Fig. 2d, g). These four cell types occupy almost the entire epithelium except at the two prominent longitudinal folds, which contain only nongranulated cells that are devoid of aminopeptidase reactivity (Fig. 2d, e). The mucus cells, which are dispersed in the epithelium do not show any aminopeptidase reactivity either. The control section does not show any reaction product (Fig. 2f).

Hepatopancreas

The hepatopancreas comprises a large number of acini (Fig. 2h). The apical part of the acinar cells near the lumen exhibits intense aminopeptidase reactivity (Fig. 2j). The control section shows no reaction of aminopeptidase (Fig. 2i).

DISCUSSION

In this study epithelial cells of the abalone digestive tract is classified into 3 types. The granulated cells (GC) are so called because they contain dense granules (serous type) with different sizes. This cell type could correspond to secretory cells as reported by Campbell (1965) and Chitramvong et al. (2000). In contrast to these earlier works we could identify at least four subtypes of these cells in various parts of the digestive tract because of their well preserved characteristics in semithin plastic sections. All GC except those in the stomach exhibit the aminopeptidase activity, which overlaps on the granulated area of the cytoplasm. There is only one type of nongranulated cell (NC), which does not exhibit aminopeptidase activity. There are at least 2 types of mucus cells (MC), in contrast to only one type of mucin producing cell reported by Campbell (1965) and Chitramvong et al. (2000). The first type of MC appears like goblet cells containing large mucin granules in the apical part, which tend to be dissolved away as shown in buccal cavity, esophagus, and stomach; whereas the second type is usually loaded with small tightly packed mucin granules as shown in the crop and intestine. Again the identification of these two subtypes of mucus cells is possible because of the use of plastic embedment. The presence and distribution of proteolytic enzyme was studied by detecting aminopeptidase (AP) reaction in different regions of the alimentary tract, from the buccal region to the anus. Almost all parts of the digestive tract show positive AP activities restricted at the brush border of the epithelial cells or in the lumen. The distinct appearance of AP reactivity was only observed in the cytoplasm of the granulated cells of buccal cavity, esophagus, esophageal pouch, as well as intestine. In addition, the intense enzyme reactivity was also detected in the acinar cells of the hepatopancreas. Hence these cells are producing zymogen granules that may contain aminopeptidase. The results agree with the work of Serviere-Zaragoza et al. (1997) who detected the pro-

teolytic activity in the hepatopancreas, crop and stomach content, and intestine and rectal fluid of the blue abalone, *H. fulgens*. The proteolytic activity observed in the intestinal and rectal fluid has optimal pH at alkaline range, whereas those from the hepatopancreas, crop, and stomach content were at acid pH. In the hepatopancreas, many proteases (three types of hydrolases and a carboxypeptidase) were detected by enzyme assays in *H. midae* (Erasmus et al. 1997, Hernandez-Santoyo et al. 1998). Moreover, trypsin and

chymotrypsin activities were also detected in the intestine and rectum by using specific-synthetic substrates and inhibitors in kinetic and electrophoresis assays (Groppe & Morse 1993, Serviere-Zaragoza et al. 1997). The AP reactivity recognized in other parts of the digestive tract observed in the present study could possibly be the result of the released enzyme being mixed with the nutrients passing through these regions of the digestive tract rather than the enzyme being synthesized by epithelial cells of these regions. This

Figure 2. (a to c.) could explain the weak AP activity at the luminal surface of the crop, the first and second intestinal parts, and in the gastric shield of the stomach.

The absence of AP activity on the secondary foldings in the crop epithelium indicates that this organ may be the main part for food absorption rather than secreting the enzymes. Our observation is in agreement with Mclean (1970) who found, by using autoradiography with ^{14}C -labeled algae, that in *H. rufescens* the crop is the major absorptive area. This author also demonstrated that the crop epithelium is permeable to phenylalanine and glucose. However, enzymes other than protease may be present in crop, because

high lipase activity was detected in the crop (Mclean 1970). Interestingly, in the intestine there is an area called the longitudinal fold (typhlosole), which does not exhibit any AP activity as most cells are nongranulated, and this structure probably is involved mainly in the absorption, whereas the rest of intestine synthesizes and secretes the protease enzyme.

ABSTRACT Effects of various degrees of starvation (0-, 5-, 10-, 15-, 20- and 25-day fasted) on tissue protein, lipid, total carbohydrate, glycogen and ash contents, as well as the ratio of soft-tissue to shell weight, were investigated in young juvenile abalone, *Haliotis discus hannai* Ino (initial shell length: 4.8 ± 0.6 mm, initial live weight: 15.0 ± 1.3 mg). Results showed that after 25-day starvation, tissue protein, lipid, total carbohydrate, and ratios of soft-tissue to shell weight decreased significantly, whereas the glycogen level remained constant, and ash content increased significantly. During the 25-day starvation, juvenile abalone lost 23.4% of protein, 19.8% of lipid, and 13.3% of total carbohydrate. The corresponding energy depletions were 226.5, 81.3, and 3.0 kJ/100 g dry body weight, respectively. The variation of energy depletion among the energy components is probably evidence of selective utilization of energy reserves by juvenile abalone, and partly a reflection of the predominance of energy components in juvenile tissues.

KEY WORDS: abalone, *Haliotis discus hannai*, young juvenile, starvation, energy reserves

INTRODUCTION

In abalone hatcheries, benthic diatoms have traditionally been used as initial foods for young juveniles. During the stage when young juveniles are at 5–10 mm of shell length, weaning on to macroalgae or artificial diet, the supply of diatoms has been identified as a major obstacle in abalone nutrition, owing to problems relating to the quality and quantity of diatoms (McCormick & Hahn 1983, Ebert & Houk 1984, Hahn 1989, Knauer et al. 1996). Starvation often occurs when juveniles are not able to ingest sufficient optimal diatoms, which is probably one of the key factors accounting for the high mortality in many abalone hatcheries all over the world.

Starvation is not an uncommon circumstance for marine invertebrates (Carefoot et al. 1993). During starvation, an organism's normal energy mobilization and metabolism is altered, and energy reserves (mainly tissue protein, lipid, and carbohydrate) are catabolized and oxidized to supply basal metabolism. Therefore, starvation must have profound effects on the organism's physiologic condition and tissue chemical content. Many researchers have conducted studies to investigate the effect of starvation on energy reserves in marine gastropods and bivalves. Results show that tissue protein, lipid, and carbohydrate play different roles in different species of marine invertebrates. Most studies on larval bivalves showed that lipid acted as the main energy reserves (Millar & Scott 1967, Corner & Cowey 1968, Holland & Spencer 1973, Whyte et al. 1987). Rodriguez et al. (1990) found that larval oyster, *Ostrea edulis*, consumed protein as the main energy source. In gastropods, available data shows that carbohydrates acted as the main energy reserves (Martin 1961, Goddard & Martin 1966). Carefoot et al. (1993) studied the effect of starvation on tissue glycogen in the northern abalone, *Haliotis kamtschatkana* of ~100–150 g live weight, and results showed that glycogen reserves in the digestive gland and foot muscle were depleted. However, there was no information on the changes of protein and lipid content during starvation.

This study is conducted to investigate the effects of starvation on the energy reserves in young juveniles of *H. discus hannai* at weaning stage, from which we can get some useful information on

the energy metabolism and nutritional requirement of abalone during this stage.

MATERIALS AND METHODS

Young Juvenile Culture and Sample

The experiment was conducted in the Mashan Sea-product abalone hatchery in Shandong Province, People's Republic of China. All the young juveniles used had been settled and grown on diatoms for 2 mo, and showed excellent performance both in growth and survival. At the beginning of the experiment, 150 young juveniles were randomly collected as the sample of Day 0, and initial shell length and live weight were measured. Three PVC hatchery tanks ($50 \times 40 \times 30$ cm) were set up as three replicates. Each tank was stocked with 500 young juveniles on black corrugated plastic plates (45×30 cm), and covered with a 1.5 mm mesh. To minimize the possibility of diatom growth contributing food for the larvae, seawater used was filtered twice with 10- μ m meshes, and the corrugated plastic plates and the tanks were thoroughly scrubbed daily. During the experimental period, water temperature ranged from 21°C to 25°C and the salinity from 31‰ to 33‰. At Day 5 and thereafter, 50 young juveniles from each tank were randomly sampled every 5 days until Day 25, and stored at -20°C for subsequent analyses. Six samples (Days 0, 5, 10, 15, 20 and 25) were achieved altogether.

Methods of Analysis

Samples were freeze-dried, and then soft-tissue was separated from the shell. The contents of protein, lipid, total carbohydrate, glycogen, and ash in soft-tissue were determined, and the ratio of soft-tissue to shell weight of each sample was calculated.

Tissue protein content ($N \times 6.25$) was calculated from the determination of total N by Kjeldahl analysis. Ash content was calculated by gravimetric analysis following loss of mass on ignition at 550°C for 24 h in a muffle furnace. Extraction of lipid was carried out by the method of Bligh & Dyer (1959), and the lipid levels were determined gravimetrically.

Total carbohydrate content was determined by the methods of Dubois et al. (1956), and modified by Towle and Giese (1966). D-glucose was used as a calibration standard. Thirty milligrams of soft-tissue were boiled for 10 min with 3 mL 15% TCA, then the

*Corresponding author. E-mail: kmai@ouc.edu.cn

mixture was centrifuged at 3,500 rpm for 10 min. TCA (15%) was added to the supernatant to the total volume of 10 mL. Two milliliter of this mixture was mixed with 1 mL 5% phenol and 5 mL concentrated sulfuric acid ($\rho = 1.84$). The mixture was allowed to stand for 10 min and then was shaken and placed in a water bath at 30°C for 15 min. The absorbance at 490 nm was measured spectrophotometrically. Total carbohydrate content was calculated as amount of released glucose (mg) per mg soft-tissue $\times 100$.

Glycogen content was measured by the method of Handel (1965), and glycogen was used as a calibration standard. Fifteen milligrams of soft-tissue were boiled with 1 ml 30% KOH for 1 h. The mixture was precipitated with 95% ethanol and glycogen determined by the anthrone method. Tissue glycogen content was calculated as amount of released glycogen (mg) per mg soft-tissue $\times 100$.

Statistical analysis

Data from each sample were subjected to one-way ANOVA and Duncan test to determine difference in means. Prior to analysis, data on percentages were transformed using squared root of arcsine, to make the variance independent of the mean; alpha levels for all tests were set at 0.05. Statistical analysis was performed using Systat package.

RESULTS

Shell length, live weight, and tissue chemical composition of juvenile abalone are shown in Table 1. Shell length maintained almost the same within the first 15 days, then there was a slight increase in shell length. Meanwhile, live weight showed a declining trend. However, these changes in shell length and live weight during the 25-day starvation were not statistically different.

Tissue protein content decreased dramatically from 53.8 to 41.2% during starvation, and there was a significant difference between the batches of Day 0–5 and the batches of Day 10–25 ($P < 0.05$). After Day 10, protein content kept almost constant. The decreased protein content at Day 25 amounts to 23.4% of the initial tissue protein (Day 0).

Tissue lipid content decreased continuously from 11.6% to 9.3% during the starvation period. After Day 15, tissue lipid was significantly lower than the initial value ($P < 0.05$). Lost lipid in the juvenile abalone at Day 25 amounts to 19.8% of the initial content (Day 0).

Total carbohydrate content also declined significantly from 12.9% to 11.2%. In the early period of starvation (from Day 0 to 5), there were no significant changes in total carbohydrate content. At Day 10, however, the total carbohydrate content declined sig-

nificantly ($P < 0.05$), and after that time it remained almost the same. The decline in total carbohydrate by Day 25 amounted to 13.3% of the initial value (Day 0).

A slight declining trend, from 4.8% to 4.6%, was observed in the tissue glycogen during the experimental period, but there was no overall significant difference ($P > 0.05$).

Tissue ash content increased significantly from 12.7% to 24.1% with the prolonged time of starvation ($P < 0.05$). Ash content in larvae of Day 20 and 25 nearly doubled that of Day 0.

The ratio of soft-tissue to shell weight decreased significantly from 0.26 to 0.12 ($P < 0.05$). And the amount declined during Day 0 to Day 10 was larger than that happened in the period from Day 15 to 25.

DISCUSSION

In the present study, almost the same shell length was maintained within the first 15 days, then there was a slight increasing trend, though this change did not have any statistical significance. This means either that the juvenile abalone might be still able to obtain limited nutrients from the environment to support shell growth, or that shell could grow using the limited nutrients stored in abalone tissues. Meanwhile, live weight showed a more obvious decreasing trend during the 25-day starvation, though the change in live weight was not statistically different either. The significant losses of organic matters (protein, lipid, and carbohydrate) in abalone tissues demonstrated that the young juveniles obtained very little nutrients from the environment. The loss of live weight, due to organic matter decrease, was probably compensated by water refilling in tissues. Hence, the results and conclusions in this study were not significantly affected by exogenous nutrients.

The tissue organic matter decreased continuously with the time of starvation suggesting that the energy reserves (protein, lipid, and total carbohydrate) were catabolized and oxidized to supply the energy required for metabolism. The decreases of tissue reserves mainly occurred during the first 15 days (protein), or 20 days (lipid and carbohydrate), and then the declines were at slower and more constant rates. Previous studies also showed that the decline of energy reserves was most rapid during the first few days during starvation in some marine invertebrates (von Brand et al. 1957, Duerr 1965, Carefoot et al. 1993). During the period of starvation, tissue protein, lipid and total carbohydrate content declined significantly, but there was little change in glycogen content. Taking the mean values of protein, lipid, and total carbohydrate content lost by the juveniles after 25 days of starvation, and converting to joule equivalents (Beukema & de Bruin 1979), it is apparent that juvenile abalone obtained more energy from protein

TABLE 1.

Tissue chemical composition in juvenile abalone *Haliotis discus hannai* Ito under different starvation.

(226.5 kJ/100 g dry weight) than lipid (81.3 kJ/100 g dry weight) and total carbohydrate (3.0 kJ/100 g dry weight). The constant content of glycogen indicated either that glycogen was not in great demand or that it was resynthesized from other constituents by glyconeogenesis. Further studies into glycogen metabolism in juvenile abalone should be carried out.

The variation of energy from different substrates probably means that juvenile abalone have selective utilization of energy reserves during starvation. However, the higher energy lost from protein may be partly due to its predominance in young juveniles. There have been different results of energy reserve usage elicited by different researchers, even from the studies on the same species of invertebrates. A number of studies on energy reserves in larval oysters, *Ostrea edulis*, during metamorphosis showed that lipid acted as the major energy supplier (Millar & Scott 1967, Holland & Spencer 1973). Results from Bartlett (1979) and Rodriguez et al. (1990) indicated that in *Ostrea edulis* and *Crassostrea gigas*, tissue protein supplied most of the energy during metamorphosis. The disagreement of these results can possibly be attributed to the different experimental conditions, and the nutritional status, of oyster larvae. Furthermore, Millar & Scott (1967) pointed out that the role of energy reserves in energy metabolism varies with the developmental stages of animals. Results of the present study dif-

fered from that of Carefoot et al. (1993), which showed that tissue glycogen acted as the main energy supplier during starvation. Available evidence suggests that energy metabolism of abalone is based on the utilization of carbohydrates, because their natural diet is rich in carbohydrates (Painter 1983), and similarly, abalone tissue contains rich stores of glycogen (Webber 1970, Knauer et al. 1994). In larval abalone, however, energy metabolism may differ largely from that in the adult. In general, juvenile animals require more protein per unit of body weight because their growth rate is higher than that of older individuals (Mercer et al. 1993). In the wild, larval and juvenile abalone might ingest diatoms with high levels of protein, because the protein content of benthic diatoms ranges widely from 3.5% to 47% (Ansell et al. 1964, Darley 1977). In juvenile abalone, there are higher contents of tissue protein and lipid than in older individuals (Mai et al. 1995), but lower glycogen content. There is probably a relationship between the initial biochemical composition and the role of various energy reserves during starvation.

INFLUENCE OF DIETARY LIPID SOURCES ON GROWTH AND FATTY ACID COMPOSITION OF JUVENILE ABALONE, *HALIOTIS DISCUS HANNAI* INO

WEI XU, KANGSEN MAI,* WENBING ZHANG, ZHIGUO LIUFU, BEIPING TAN, HONGMING MA, AND QINGHUI AI

The Key Laboratory of Mariculture (Education Ministry of China), Ocean University of China, Qingdao 266003, People's Republic of China

ABSTRACT A study was conducted to evaluate the effects of dietary lipid sources on the growth and fatty acid composition of juvenile abalone *Haliotis discus hannai* Ino. Four triplicate groups of juvenile abalone (initial weight: 0.13 ± 0.04 g; initial shell length: 10.23 ± 1.48 mm) were fed with one of four semipurified diets containing 3.5% of dietary lipid from either tripalmitin (TP), soybean oil (SO), linseed oil (LO), or 20:5n-3-enriched fish oil (FO), respectively, and were reared for 120 days in a recirculation water system. Results showed that the growth rate of abalone was significantly affected by dietary lipid sources ($P < 0.05$). The dietary lipid, FO produced the highest weight gain rate (WGR, 413.2%), closely followed by LO (389.0%) and SO (382.4%). These three WGR values were not significantly different to each other. However, abalone fed the TP diet showed a significantly lower WGR (267.3%). Carcass moisture and protein were independent of dietary treatment, but the TP diet resulted in significantly lower carcass lipid. The fatty acid profile in abalone carcass reflected that of dietary lipids, especially the unsaturated fatty acids. It appears that *H. discus hannai* have a capacity to synthesize 20:5n-3, 20:4n-6 and 22:6n-3 from 18-carbon PUFAs and even from 16:0 through elongation and desaturation. However, the capacity seems to be insufficient to support the maximum growth of abalone.

KEY WORDS: *Haliotis discus hannai*, lipid sources, fatty acid composition, growth, feeding and nutrition mollusk

INTRODUCTION

Dietary lipid plays important roles in providing concentrated energy, essential fatty acids (EFA) and some other nonfat nutrients to organisms. The qualitative and quantitative requirements of fish and crustaceans have been extensively studied (NRC 1993, Sargent et al. 2002). Previous studies have demonstrated that dietary lipid sources may influence the growth, survival, feed efficiency, and fatty acid composition of aquatic animals including fish and shrimp, and that the qualitative and quantitative requirements of fish and crustaceans for lipids considerably differ with different species (NRC 1993, D'Abramo 1997, Sargent et al. 2002). Results suggest that many marine fish and prawns require n-3 highly unsaturated fatty acids (HUFA), particularly eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) to maintain normal physiology and growth. For some marine species, it is believed that DHA appears to be superior to EPA (Watanabe 1993, Mourente & Toche 1993, Xu et al. 1994, Rodriguez et al. 1997).

For mollusks, however, less is known about the nutritional value of different lipid sources. According to available information, the polyunsaturated fatty acids (PUFA) of n-3 and n-6 families are able to enhance the growth of *Haliotis discus hannai* and *H. tuberculata*. Especially, 20:5n-3 played a more prominent role in abalone nutrition (Uki et al. 1986, Mai et al. 1996a, Mai et al. 1996b). It is suggested that with different EFA composition, lipids from different sources have different nutritional values for abalone. However, no significant differences were found in the growth of *H. fulgens* fed the different oil types, olive, corn, linseed, and cod liver oils (Durazo-Beltrán et al. 2003). There is no information available about the effects of different lipid sources on the growth of *H. discus hannai*. This study was conducted to evaluate the effects of different dietary lipid sources on the growth, survival, and carcass composition of juvenile abalone *H. discus hannai*, which would provide useful information for abalone aquaculture.

MATERIALS AND METHODS

Experimental Diets and Design

Experimental basal diet was formulated to provide 28% crude protein from casein and gelatin (Table 1), which is considered to be sufficient to maintain optimum growth for *H. discus hannai* (Mai et al. 1995a). Tripalmitin (TP), soybean oil (SO), linseed oil (LO) or fish oil (FO) was individually added to the basal diet to produce four experimental diets, respectively. Dietary lipid level was maintained at 3.5%, which was considered to be an optimal level for this abalone (Mai et al. 1995b). The main fatty acid compositions of SO, LO and FO were determined by GC, and the results are given in Table 2. Procedures for diet preparation and storage were the same as those previously described by Mai et al. (1995a).

Animal Rearing

Abalone (initial weight: 0.13 ± 0.04 g; initial shell length: 10.23 ± 1.48 mm) were derived from a spawning at Mashan Fisheries Co. Shandong, China. Shell length was measured with calipers to the nearest 0.02 mm. The individual abalone was superficially dried with tissues and then weighed to 0.01 g using an electronic balance. Growth trial was conducted in a recirculation water system. Twenty-five juvenile abalone were stocked in a rearing unit, a plastic basket (20 cm \times 20 cm \times 10 cm) placed in a glass aquarium (45 cm \times 25 cm \times 35 cm), as one replicate. There were three replicates for each of the four dietary treatments.

Prior to initiation of the experiment, abalone were placed in glass aquariums and conditioned with the basal diet for 1 wk. Animals were hand-fed with the test diets at a rate equaling 5% to 10% of wet body weight once daily at 17:00. Every morning, feces and excess feed were removed to maintain water quality. The feeding trial was run for 120 days. During the 120-day experiment, water temperature was maintained at 18°C to 25°C, salinity 31 to 35, pH 7.6 to 8.0. Dissolved oxygen was not less than 6 mg/L, and there were negligible levels of free ammonia and nitrite.

^b Mineral mix: each 1000 g of diet contained NaCl, 0.4 g; MgSO₄ · 7H₂O, 6.0 g; NaH₂PO₄ · 2H₂O, 10 g; KH₂PO₄, 12.8 g; Ca(H₂PO₄)₂ · H₂O, 8 g; Fecitrate, 1.0 g; Ca-lactate 1.4 g; ZnSO₄ · 7H₂O, 141.4 mg; MnSO₄ · 4H₂O, 64 mg; CuSO₄ · 5H₂O, 12.4 mg; CoCl₂ · 6H₂O, 0.4 mg; KIO₃, 1.2 mg.

Sample Collection and Analysis

At the termination of the experiment, animals were not fed for 3 days. All abalone were collected from the cages, counted, weighed, and measured then immediately frozen (-70 °C) for subsequent analyses. Growth was expressed as weight gain rate (WGR, %) and daily increment in shell length (DISL, μm/d). The calculation formulae are as follows:

TABLE 2.

Fatty acid composition of dietary lipid sources (% area).

Fatty Acid	Lipid Source ^b		
	SO	LO	FO
14:0	0.51	0.22	ND
16:0	9.42	6.41	ND
16:1	0.24	0.16	ND
18:0	3.82	3.58	2.02
18:1n-9	21.81	21.31	3.43
18:1n-7	0.90	1.20	1.05
18:2n-6	50.60	15.49	0.82
18:3n-3	5.70	49.03	3.11
20:4n-6	ND	ND	1.09
20:5n-3	ND	ND	49.77
22:6n-3	ND	ND	21.60

ND, undetectable (<0.01 g/100 g fatty acids); SO, soybean oil; LO, linseed oil; FO, fish oil.

$$\text{WGR (\%)} = (\text{Wt} - \text{Wi}) / \text{Wi} \times 100$$

$$\text{DISL (\mu m/d)} = [(\text{SLt} - \text{SLi}) / \text{t}] \times 1000$$

Where, Wt and Wi are final and initial mean weight (g), respectively; SLt and SLi are final and initial mean shell length (mm), respectively.

The procedures for analysis of the fatty acid profiles in lipid sources and abalone carcass were modified from those described by Metcalfe et al. (1966). Briefly, fatty acid methyl esters were separated and quantified by the gas chromatograph equipment (HP5890) with a fused silica capillary column (007-CW, HP) and a flame ionization detector. The column temperature was programmed to rise from 150° up to 200° at a rate of 15° min⁻¹, from 200° to 250° at a rate of 2° min⁻¹.

Proximate analyses of the diets and abalone soft-body samples to determine protein, lipid, ash, and moisture levels were conducted using standard procedures (AOAC 1995).

Statistical Analysis

All percentage data were square-root arcsine transformed prior to analysis. Data were submitted to 1-way analysis of variance using the STATISTICA™ package. When significant differences ($P < 0.05$) were found, means were compared using the Tukey's test.

RESULTS

Survival and Growth

The data of abalone survival and growth performances are presented in Table 3. Analysis of variance showed that there was no significant difference in survival, which ranged from 90% to 96%, among the dietary treatments. However, weight gain rate (WGR) of the animals was significantly affected by the different lipid sources. Abalone fed tripalmitin (TP) diet had a significantly lower WGR (267.32%). Meanwhile, those fed the diet with EPA-enriched fish oil (FO) showed the highest WGR (413.19%). Soybean oil (SO) and linseed oil (LO) resulted in the WGRs of 382.43% and 389.04%, respectively. These later three WGR values were not significantly different from each other. The trend of daily increment in shell length (DISL) changing with different dietary lipids was similar to that of WGR. However, the effects of dietary lipids on DISL were not significant.

Fatty acid Composition in Carcass

Fatty acid composition in abalone carcass is shown in Table 4. Different dietary lipids significantly influenced the fatty acid patterns in carcass, particularly the polyunsaturated fatty acids (PUFA). Abalone fed TP accumulated a higher level of palmitic acid (16:0) in tissues. There were significantly higher levels of EPA (20:5n-3, 12.0%) and DHA (22:6n-3, 2.6%) in the abalone fed diet with FO than those in all other treatments. The highest values of linoleic acid (18:2n-6) and arachidonic acid (20:4n-6, ARA) were found to be 1.64% and 6.03%, respectively, in abalone fed the diet with SO. Abalone fed LO had the highest values of linolenic acid (18:3n-3, 2.97%), and had a significantly higher level of EPA (7.86%) than those fed the diet with TP (5.87%) or with SO (4.61%), but it was significantly lower than that resulted from feeding FO diet (12.0%). Contents of carcass EPA in all experimental treatments were generally higher than those of DHA.

Carcass Proximate Composition

Data on abalone carcass moisture, protein, and lipid contents are given in Table 5. Among the dietary treatments, there were no

significant differences in abalone carcass moisture ranging from 77.1% to 78.1%, and in abalone carcass protein ranging from 64.8% to 66.2%. However, the significant effect of the dietary treatments on abalone carcass lipid contents was observed. The diet containing TP resulted in significantly lower carcass lipid (4.7%) than those containing either SO (6.1%), LO (6.0%) or FO (5.6%).

DISCUSSION

Previous studies on the requirement of *H. discus hannai* for essential fatty acids using purified diets or macroalgae demonstrated that EPA (20:5n-3) played a prominent role in the nutrition of abalone, and linoleic acid together with other n-3 and n-6 PUFA also contributed to the faster growth of *H. discus hannai* (Uki et al. 1986, Mai et al. 1996a, Mai et al. 1996b). During the 120-day feeding trial of the present study, the mean body weights of abalone in all the four treatments increased by high percentages, from 267.3% to 413.1%. This means that, on one hand, the carcass storage of essential fatty acids are probably able to support abalone growth for a long period. On the other hand, abalone is probably able to biosynthesize essential fatty acids, to a certain extent, from

different lipid sources. It can be seen from Table 4 that the carcass of abalone fed the TP diet showed fairly high levels of 18:2n-6, 20:4n-6 and 20:5n-3, indicating that active elongation and desaturation of palmitic acid take place in *H. discus hannai*. Similarly, the highest level of 20:4n-6 in carcass was found in the treatment with dietary SO that contains the highest level of 18:2n-6 (50.6%), and significantly higher carcass level of 20:5n-3 was observed in abalone fed the diet with LO, which contains the highest level of 18:3n-3 (49.0%), than those fed diets with TP or SO. It is suggested that *H. discus hannai* have the ability to bio-convert 18:2n-6 to 20:4n-6, and 18:3n-3 to 20:5n-3. Similar findings have been reported in *H. laevigata* (Dunstan et al. 1996) and *H. fulgens* (Durazo-Beltrán et al. 2003).

Abalone is probably able to biosynthesize highly unsaturated fatty acids (HUFA), to a certain extent, by elongation and desaturation of short-chain fatty acids, however, the differences in weight gain rate were observed among the dietary treatments of different lipid sources (Table 3). This is probably due to the fact that the capacity of abalone to biosynthesize essential fatty acids is insufficient to support normal growth, and that biosynthesis of essential fatty acids is an energy-consuming process that could suppress the

growth of abalone fed diets with short-chain fatty acids. The present study and previous ones have demonstrated that HUFAs are superior to short-chain PUFAs in enhancing abalone growth (Uki et al. 1986, Mai et al. 1996a, Mai et al. 1996b). Lipid sources, rich in HUFA, mainly come from marine origins, such as fish oils. However, fish oils are increasingly in short supply globally, and

intensive studies are underway on fish oil substitution in the aquaculture feed industry. Hence, further studies should be conducted to determine the optimal ratio of fish oils to plant oils in diets for abalone. Durazo-Beltrán et al. (2003) did not find significant differences in the growth of *H. fulgens* fed the different oil types (olive, corn, linseed, and cod liver oils). The authors assumed that the lack of a growth response to the different lipid sources and different levels of HUFA may be due to insufficient duration (75 days) of the experiment to achieve an essential fatty acid deficiency.

Fatty acid biosynthesis in fish and crustaceans has been extensively studied and it has been shown that the overall conversion of 18-carbon PUFA to HUFA occurs poorly in the marine species studied so far (Ito & Simpson 1996, D'Abramo 1997, Sargent et al. 2002). For abalone, however, there is still no direct evidence on the pathways of fatty acid biosynthesis. Further investigations are needed to elucidate detailed pathways of fatty acid biosynthesis and their regulation in abalone and other mollusks.

DIETARY PANTOTHENIC ACID REQUIREMENT OF JUVENILE ABALONE, *HALIOTIS DISCUS HANNAI* INO

WEI ZHU, KANGSEN MAI,* BEIPING TAN, AND GETIAN WU

The Key Lab of Mariculture (Ministry of Education), Ocean University of China, Qingdao 266003, People's Republic of China

ABSTRACT Juvenile abalone, *Haliotis discus hannai* Ino, of 0.55 ± 0.02 g in body weight, and 15.48 ± 0.31 mm in shell length, were fed with six purified diets containing 0, 9.8, 19.8, 39.7, 79.4, 158.5 mg Ca-pantothenic acid/kg diet for 16 wk. The Ca-pantothenic acid was microbound with sodium alginate, and other water-soluble vitamins were encapsulated with sodium alginate, by an emulsion coacervation process, prior to supplementation in experimental diets. The dietary Ca-pantothenic acid concentration did not affect the body composition of abalone. Weight gain (WG), daily increment in shell length (DISL), and tissue pantothenic acid were significantly affected by dietary pantothenic acid. According to broken-line regression analysis, 21 mg Ca-pantothenic acid/kg diet was found to satisfy the maximum growth of abalone, whereas on the basis of the pantothenic acid concentration in the viscera and muscle of the experimental abalone, 24 and 26 mg Ca-pantothenic acid/kg diet were required, respectively. Hence, the optimum dietary Ca-pantothenic acid requirement for *H. discus hannai* Ino is estimated to be 26 mg/kg diet.

KEY WORDS: abalone, *Haliotis discus hannai* Ino, Ca-pantothenic acid, requirement, feeding and nutrition, molluscs

INTRODUCTION

Pantothenic acid (PA) has crucial roles in intermediary metabolism as a constituent of coenzyme A (CoA) and phosphopantotheine. As a part of coenzyme A, pantothenic acid transfers acyl groups in enzymatic reaction such as oxidation of pyruvate and fatty acids (NRC 1983).

Pantothenic acid deficiency signs in fish are usually growth retardation, anorexia, abnormal swimming behavior, and death (Halver 1989). The most common signs of PA deficiency are clubbed gill and fusion of gill filaments (NRC 1981, Wilson et al. 1983, Butthep et al. 1985, Masumoto et al. 1994). Dietary PA requirement for maximum growth and prevention of deficiency signs have been reported to be 10–20 mg/kg diet for salmonids (NRC 1981), 10 mg/kg of diet for channel catfish (Murai & Andrews 1979, Wilson et al. 1983) and blue tilapia (Roem et al. 1990, Soliman & Wilson 1992), and 30–50 mg/kg for common carp (Ogino 1967).

Masumoto et al. (1994) suggested that free PA tissue concentrations measured by radioimmunoassay (RIA) are a more sensitive indicator of pantothenic acid intake in rainbow trout than reduction in appetite or reduced growth.

Abalone are large algivorous marine mollusks of the genus, *Haliotis* (*Gastropoda*, *Prosobranchia*, *Archaeogastropoda*, *Haliotidae*). They are the most commercially important gastropods in aquaculture. Water-soluble vitamin requirements of the abalone, *H. discus hannai*, were recently reported to include: vitamin C, vitamin B₁, inositol, and biotin (Mai 1998, Mai et al. 2001, Wu et al. 2002, Zhu et al. 2002). The objective of this study is to investigate the effects of dietary PA on survival, growth, and tissue PA concentration and further to estimate the optimum level of dietary PA for the abalone, *H. discus hannai*.

MATERIALS AND METHODS

Experimental Diet

Formulations of the experimental diets and their proximate composition are shown in Table 1. Crude protein level of the experimental diets was 28.2%, which is considered to be sufficient to maintain optimum growth for *H. discus hannai* (Mai et al.

1995b). Soybean oil and menhaden fish oil (1:1) was used as the basal lipid source. Dietary lipid level was 3.75%, which was sufficient to support optimum growth and provide enough EFA for the abalone (Mai et al. 1995a). The vitamin (except for Ca-PA) and mineral mixture were slightly modified from those used by Uki et al. (1986). Six experimental diets were formulated from purified ingredients to provide graded levels of Ca-pantothenic acid ranging from 0–158.5 mg/kg diet.

Ca-PA was microbound with sodium alginate prior to supplementation to the experimental diet. One gram Ca-PA was mixed well with 1-g sodium alginate; appropriate water was added and mixed. The paste was lyophilized for 24 h, and then ground to a powder (passed through a sieve with 125- μ m pore size). Other water-soluble vitamins were microencapsulated with sodium alginate by an emulsion coacervation process prior to supplementation to the experimental diets. The method of microencapsulation was modified from that described by Bodmeier and Wang (1993). A portion of sodium alginate solution (2%, w/w) containing 2% (w/w) of the vitamins to be microencapsulated, was mixed with another portion of oil containing 6.74 g/L of Span 80, stirred at 400 rpm for 15 min. The emulsified solution was slowly poured into 1% (w/w) CaCl₂ solution, with continuous stirring for 1 min, and then filtered with a vacuum filter. The harvested microcapsules were washed with cyclohexane and non-water alcohol in turn, to remove oil and water, dried at room temperature, and then kept at -20° until use. The actual quantities of Ca-pantothenic acid in diets were measured by HPLC (Table 2).

Procedures for diet preparation were based on the method of Mai et al. (1995a). All the ingredients (passed through a sieve with 125 μ m pore size) were mixed thoroughly and were made to a paste by gradually adding water (about 120%, v/w). The paste was shaped into 0.5-mm thick sheets, which were cut into 1-cm² flakes. The flakes were dipped in an aqueous solution of CaCl₂ (5%, w/v) for about 1 min, and then the surplus solution was drained naturally. The diet flakes were sealed in a sample bag and stored at -20° until use.

Experimental Procedures

Abalone juveniles (*H. discus hannai*), of 0.55 ± 0.02 g average weight and 15.48 ± 0.31 mm mean shell length, used in this experiment, were from a spawning at Mashan Fisheries Co., Shan-

dong Province of China. Thirty abalone were placed into each rearing unit, a plastic cage (20cm × 20 cm × 15 cm) with a corrugated plastic plate as a shelter. There were three replicates for each of the six dietary treatments. All the cages were distributed randomly in a rectangle pool (1 m × 1 m × 6 m). Fresh seawater, flowing through 30-μm primary sand filters, then through 10-μm secondary composite sand filters, was continuously supplied to the pool. The flow rate was about 0.5 L per min per cage. Cages were kept in dim light by screening a large drape above. Before the experiment, the abalone underwent a week conditioning period. The animals were fed with test diets once a day at 17:00 at a satiation level with a little leftover (5% to 10% of abalone wet weight per day). The plastic cages were cleaned at 8:00 o'clock every morning to remove the uneaten feed and feces during the experimental period. The temperature of the water was 15 °C to 25 °C, salinity 30‰ to 34‰, pH 7.6 to 7.9. Dissolved oxygen was not less than 7 mg/L, and there were negligible levels of free ammonia and nitrite. The Ca-pantothenic acid in the seawater was below the level of detection. The whole feeding experiment was conducted for 16 wk.

Sample Collection and Analysis

At the termination of the experiment, all abalone from each replicate, were fasted for 3 days, then removed from the cages, counted, weighed, measured, and then frozen in -70° for subsequent chemical analysis. Growth performance is expressed as weight gain (WG, %) and daily increment in shell length (DISL, μm/day). The calculation formulae are as follows:

$$WG (\%) = [(Wt - Wi) / Wi] \times 100$$

$$DISL (\mu\text{m}/\text{day}) = [(SLt - SLi) / t] \times 1000$$

where, Wt, Wi are final and initial mean weight (g), SLt, SLi are final and initial mean length (mm), respectively; and t is the feeding experiment period (days).

TABLE 2.

Composition of vitamin mix and Ca-pantothenic acid (Ca-PA) in the diet (on dry weight basis).

Vitamin Mix (Without Ca-PA) ^a		Actual Ca-PA Content in Test Diet (mg/kg Diet)	
Vitamin	1000 g Diet	Diet	Ca-PA
Thiamin HCl	120 mg	D0	0
Riboflavin	100 mg	D10	9.4 ± 0.87
Folic acid	30 mg	D20	19.8 ± 2.35
PABA	400 mg	D40	39.7 ± 3.74
Pyridoxine HCl	40 mg	D80	79.4 ± 6.88
Niacin	200 mg	D160	158.5 ± 10.73
Inositol	4000 mg		
Biotin	12 mg		
Vitamin E	450 mg		
Menadione	890 mg		
VB ₁₂	0.18 mg		
Ascorbic acid	4000 mg		
Retinol acetate	100000 IU		
Cholecalciferol	2000 IU		

^a 400 mg ethoxyquin was used as an antioxidant.

Proximate analyses to determine protein, lipid, and moisture levels in diets and abalone carcass were conducted using standard methods (AOAC 1995). Moisture content was calculated following drying in an oven at 105° for 24 h. Crude protein was estimated by the Kjeldahl method. Crude lipid was determined after ether extraction by the Soxhlet method.

Water Stability of Ca-Pantothenic Acid in Experimental Diets

The leaching measurement of dietary Ca-PA was carried out with the modified method of Zhu et al. (2002). The experimental feeds, together with a control feed supplemented with 200 mg/kg crystalline Ca-pantothenic acid, were put into packets of 100-mm screens and placed onto the bottom of experimental cages without abalone. Temperature and flow rate were 20 ± 0.8° C and about 0.5 L per min per cage that matched those of the experiment respectively. At the end of allotted times (0, 1, 2, 6, 12 h, respectively), the remaining diets were removed from the cages and freeze dried for 24 h. Then the Ca-PA concentrations were measured by HPLC.

The Ca-PA levels in abalone tissues and diets were analyzed with HPLC by a method modified from the HP operation manual (HP 1999). Weighted viscera and muscle tissues were homogenized with 3 mL of Millipore water. Homogenates were deproteinized with saturated barium hydroxide and 10% zinc sulfate. Samples were then centrifuged (6000g for 10 min.) and the supernatants were filtered through a 0.45-μm filter prior to being analyzed by HPLC with an ODS hypersil column (4 × 250 mm). The mobile phase A was 15 mM phosphate buffer (pH 7.5) and mobile phase B was methanol. A: B = 70: 30 was used as eluant. The flow rate was 0.8 mL/min. Pantothenic acid was detected with a diode array detector (DAD) and detecting wavelength was 245 nm. The Ca-PA (from Sigma Co.) was solved in Millipore water as a standard.

Statistical Analysis

All percentage data were square-root arcsine transformed prior to analysis. Data from each treatment were subjected to one way

ANOVA. When overall differences were significant at less than 5%, Tukey HSD test was used to compare the mean values between individual treatments. Ca-PA requirements of the juvenile abalone were estimated from weight gain (WG), daily increment in shell length (DISL), PA concentrations in the viscera and muscle using broken-line analysis (Robbins et al. 1979). Statistical analyses were performed using the STATISTICA™ package.

RESULTS

Leaching

The leaching of microbound Ca-PA in the experimental diets was significantly lower than that of crystalline Ca-PA (Table 3). The retentions of microbound Ca-PA in the diets were about 80% after 2-h immersion in seawater and about 40% after 12-h. Meanwhile, the corresponding retentions of crystalline Ca-PA in the control diet were 53.5% and 28.5% respectively. There was no significant difference in water stability among the diets containing different levels of microbound Ca-PA at each sampling time.

Survival, Weight Gain and Daily Increment of Shell Length

There were no significant differences in survival of the abalone among the dietary treatments (Table 4), which ranged from 90% to 97.8%. The weight gain (WG) was significantly affected by dietary Ca-PA after the 16-wk rearing period. The WG was lowest in the group fed Ca-PA free diet and increased from 92.0% to 147.8% as the dietary PA increased from 0 to 19.8 mg/kg and leveled off when dietary PA further increased. The change of the values of DISL was similar to WG (Table 4). It increased from 45.5 to 64.0 $\mu\text{m}/\text{day}$ when dietary Ca-PA increased from 0 to 19.8 mg/kg and reached a plateau when dietary Ca-PA further increased. Based on broken line analysis, the relationship between WG and dietary PA level (X) is $Y = 150.24 - 2.787(21 - X)$, and that of DISL is $Y = 63.88 - 0.964(20 - X)$.

Carcass Composition

The results of carcass composition are shown in Table 5. There were no significant differences in soft body protein, lipid or moisture among all the treatments ($P > 0.05$) after feeding with the

feeds containing graded levels of Ca-PA for 16 wk. Soft body protein, lipid, and moisture of the experimental abalone ranged from 52.7% to 55.0%, 7.5% to 8.1%, and 75.7% to 79.5%, respectively.

Tissue Pantothenic Acid Concentration

Visceral and muscle concentrations of PA are shown in Table 6. They were significantly affected by the dietary Ca-PA level. PA content in the viscera increased from 5.82 to 10.74 µg/g wet tissue when dietary PA increased from 0 to 39.7 mg/kg diet, then leveled off when dietary PA further increased. Changes in the PA contents in muscle were similar to those in the viscera, but were much lower than those in viscera, ranging from 1.25–4.71 µg/g. Both of them responded in a broken-line model to dietary Ca-PA levels, the breakpoints were 24 and 26 mg/kg respectively.

DISCUSSION

Leaching of vitamins from fish feed is a serious problem in aquaculture: immersion of feed, especially if prolonged, may lead to very high rates of vitamin depletion and to insufficient or unbalanced supplies of these micronutrients to farmed animals (Marchetti et al. 1999). In the present study, to reduce leaching of dietary water-soluble vitamins during the period before being consumed, Ca-pantothenic acid was treated with microbinding with sodium alginate, and other water soluble vitamins were microencapsulated with sodium alginate by an emulsion coacervation process before supplementation. A leaching test showed that the leaching rates for the first 2 h of dietary Ca-PA in seawater was significantly reduced from 46.5% to 21.1% by the above mentioned processes (Table 3). According to previous studies, it is reliable to determine the effect of dietary pantothenic acid on abalone using these experimental feeds (Zhu et al. 2002).

The optimum PA requirement is 26 mg/kg diet according to the

TABLE 6.

Pantothenic acid (PA) in viscera and muscle of juvenile abalone, *Haliotis discus hannai* fed diets with graded levels of PA for 16 weeks.

Dietary Number	Dietary PA (mg/kg)	Visceral PA (µg/g)	Muscle PA (µg/g)
0	0	5.82 ± 0.65 ^{a1}	1.25 ± 0.19 ^{a1}

results of this study, which is higher than 10–20 mg/kg for salmonids (NRC 1981), 10 mg/kg of diet for channel catfish (Murai & Andrews 1979, Wilson et al. 1983), and blue tilapia (Roem et al. 1990, Soliman & Wilson 1992) but lower than 30–50 mg/kg for common carp (Ogino 1967). Abalone are slow feeders. The extended period before consuming food increases the leaching of nutrients, including water-soluble vitamins like Ca-PA. In the present study, leaching of the vitamin still exists although the microbinding technique was used. If the water stability of dietary Ca-PA is further improved, the requirement of dietary Ca-PA for this species will be further reduced.

Masumoto et al. (1994) pointed out that free PA in the gill, heart, and liver were 15.2–81.5, 24.4–48.1, 68.6–83.7 nmol/g tissue of rainbow trout, and suggested that free PA in the gill and heart are sensitive indicators. In the present study, the free PA in the viscera and muscle of the abalone measured by HPLC were 5.82–11.02 µg/g viscera and 1.25–4.71 µg/g muscle respectively, and they were also significantly affected by dietary PA, indicating that they were all sensitive to PA status of the abalone.

In some fish, PA deficiency can result in various deficiency signs (NRC 1981, Wilson et al. 1983, Butthep et al. 1985, Masumoto et al. 1994). In this study, there was no other overt deficiency sign found except for poor growth. This is perhaps partly due to the bottom-living habit and slow growth of abalone (Chen et al. 1991, Wu et al. 2002, Zhu et al. 2002).

ACKNOWLEDGMENTS

The authors thank Mr. Hongming Ma and Ms. Wei Xu for their kind assistance in the biochemistry analysis and Mr. Shaobo Du for their assistance in the feeding experiment. ABSTRACT Growth, survival, and tissue biochemical composition of juvenile green abalone *Haliotis fulgens* were recorded for two temperature regimes simulating the contrasting marine conditions, one as a normal year and the other as an El Niño 1997 to 1998 event during 120 days in the laboratory. Abalones were fed *Macrocystis pyrifera* or *Eisenia arborea*. During the experiment, juveniles were sampled for biochemical analysis at the maximum temperature, which occurred at 60 days and at 120 days. Significant differences in growth of shell length and wet body weight among treatments were recorded. The highest growth (39 $\mu\text{m}\cdot\text{day}^{-1}$ and 16.0 $\text{mg}\cdot\text{day}^{-1}$) occurred in juvenile abalone within the El Niño temperature pattern and fed *M. pyrifera*. Survival rates were approximately 95% without significant differences between treatments. At maximum temperature, juveniles within the El Niño pattern had higher levels of protein in the hepatopancreas, regardless of diet. A significant interaction between temperature regimen and food was observed for glycogen in muscle, with the highest levels in juveniles fed *M. pyrifera* within the El Niño pattern. At the end of the experiment, juveniles in the normal year pattern had higher levels of lipids in the hepatopancreas. Increased levels of protein, total carbohydrates, and glycogen in muscle were present in juveniles in the El Niño pattern, regardless of diet. Juveniles fed *M. pyrifera* had higher levels of protein and lipids in the hepatopancreas and increased levels of protein, carbohydrates, and glycogen in muscle tissue, regardless of temperature regimen. The influence of diet and temperature regimen on several biochemical components closely matched their effects on growth.

KEY WORDS: biochemical composition, carbohydrates, El Niño, glycogen, green abalone, *Haliotis fulgens*

INTRODUCTION

Long-term temperature series have shown that, during El Niño oceanographic conditions, the appearance of unusually warm surface waters in the eastern tropical Pacific Ocean is one of the most prominent aspects of El Niño (ENSO) phenomenon (Philander 1990). There is an anomalous increase of sea surface temperature and a coincident drop in nutrient concentration (Jackson 1977, Zimmerman & Kremer 1984, Hernández-Carmona et al. 2001). Along the Baja California Peninsula, the maximum sea surface temperatures recorded during an El Niño was in 1997 to 1998, around 28°C (Ponce-Díaz et al. 2003b). It has been considered the most intense of the 20th century (McPhaden 1999).

The effect of temperature on the physiology of abalone includes gonadal maturation, larval development, feed consumption, ammonia excretion, oxygen consumption, growth rate, and survival (Britz et al. 1997). Thermal tolerance limits are more restrictive in larvae and recently settled individuals, but temperature affects abalone species differently. In *Haliotis fulgens* Philippi, 1845, the upper lethal limit for juveniles (1–2 cm) is 31.5°C (LT₅₀-48 h) (Leighton et al. 1981). This suggests that there was little or no direct effect of temperature during the strong El Niño event of 1997 to 1998 on survival of green abalone juveniles along the Baja California Peninsula coast, Mexico. Nevertheless, environmental fluctuations may favor the development of some diseases, as in California (USA); high temperatures may increase the mortality rate of black abalone (*H. cracherodii* Leach, 1814) affected by withering syndrome (WS) (Friedman et al. 1997). Mass mortality of black abalone was recorded after the occurrence of the 1984 El

Niño (Haaker et al. 1992). Friedman et al. (2002) found an intracellular bacterium (order Rickettsiales) as the etiologic agent for that die off.

Availability of a major food of abalone, the brown alga *Macrocystis pyrifera* (L.) C. Ag., becomes limited during El Niño events. Warm-water events lead to large-scale declines of surface canopy fronds in *Macrocystis* due to thermal stress and reduced nutrients in local nearshore areas (North 1957, North 1971, Hernández-Carmona 1987, Dayton & Tegner 1990, Ladah et al. 1999, Hernández-Carmona et al. 2001, Guzmán del Prío et al. 2003). Feed availability may be a significant factor to be considered regarding how abalone stocks may be affected during future El Niños and global warming. Along the Baja California coast, juvenile green abalone showed high variability in size, which may be an indirect effect of the 1997 to 1998 El Niño on their food supply (Guzmán del Prío et al. 2003). This study was designed to assess the survival, growth, and biochemical composition of the tissue of juvenile green abalone (*Haliotis fulgens*) under two temperature regimes that simulate the contrasting summer marine conditions during a normal year and a severe El Niño (1997–1998) while being fed the two dried brown algal diets *M. pyrifera* and *Eisenia arborea* Aresch.

MATERIAL AND METHODS

Temperature Patterns and Natural Diet

Two elevated temperature regimes (July to November), one for a normal year (18°C to 21°C) and the other El Niño 1997 to 1998 (20°C to 28°C), were simulated in tanks following the daily measurements of sea surface temperature at Bahía Asunción, Baja California Sur. The normal year data was obtained from an average

*Corresponding author. E-mail: gponce04@cibnor.mx

of 1992 to 1996, and the El Niño year from data obtained during 1997 (Fig. 1a) (Ponce-Díaz et al. 2003a). Controlled temperatures in laboratory tanks varied $\pm 2^\circ\text{C}$, which was related to the precision of the equipment used to control the seawater temperature (Fig. 1b).

In each temperature regimen, 2 brown algae, *M. pyrifera* and *E. arborea*, were used as food. *M. pyrifera* is considered a major food of abalone. Most fronds are lost during intense El Niño events (Hernández-Carmona et al. 2001). *E. arborea* is also believed to be an important species as a potential food for abalone along Baja California (Guzmán del Prío et al. 1972, Serviere-Zaragoza et al. 1998). Its populations decrease during El Niño events, but do not disappear (Hernández-Carmona et al. 2001). *M. pyrifera* and *E. arborea* (blades excluding pneumatocysts) were collected from the central coast of Baja California peninsula, Mexico. Blades were air dried and stored in cardboard boxes at 20°C to preclude deterioration. Diets were rehydrated before administration.

Experimental Procedure

Growth and survival of 312 hatchery-produced, green abalone *Haliotis fulgens* (average starting size $29.0 \text{ mm} \pm 4.3$ [sd] shell length and average starting wet body $2.37 \text{ g} \pm 1.1$ [sd] weight) were recorded for a 120 d experiment. Experimental animals were held in 16-L fiberglass rearing tanks ($50 \times 30 \times 35 \text{ cm}$, LWH). Abalone were marked with plastic tags glued to the shell. Rehydrated diets were given *ad libitum* in the afternoon at intervals of 2 days. Three replicate tanks were used for each of 4 treatment conditions: El Niño-*M. pyrifera*; El Niño-*E. arborea*; Normal-*M. pyrifera*, and Normal-*E. arborea*. Each tank contained 26 abalone

(12 tanks). Treatments were randomized among tanks. Every second morning, uneaten food and feces were removed. Micro algae growing on the inner walls of tanks were removed twice a week with a brush. Filtered ($10 \mu\text{m}$) seawater was supplied at a flow-through rate of $70 \text{ mL}/\text{min}$ giving about 6 water exchanges/day. The water was vigorously aerated. Seawater temperatures lower than 24°C were maintained with a flow trough in a chiller. Higher temperatures were maintained with 100-W heaters immersed in each tank (VISI-THERM).

Growth

Shell length was measured with a vernier caliper, and wet body weight with an electronic balance (nearest 0.001 g) at 0, 30, 58, 97, and 120 days. Dead animals were removed and replaced to maintain the standard density, although data from these animals were not used in the analysis. Daily growth rates for shell length ($\text{GR}_{\text{SL}} = (\text{SL}_f - \text{SL}_i)/T$) and wet body weight ($\text{GR}_{\text{BW}} = (\text{BW}_f - \text{BW}_i)/T$) were calculated. SL_f = mean final shell length, SL_i = mean initial shell length, BW_f = mean final wet weight, BW_i = mean initial wet weight, and T = time in days.

Biochemical Analysis

At both temperature regimes, specimens were sacrificed for composition samples twice, once at the maximum temperature (60 days after the beginning of the experiment) and the other at the end of the study (120 days after the beginning of the experiment). On each date, fifteen animals from each treatment were sampled at random. The hepatopancreas and shell muscle were dissected, weighed (wet wt), and stored at -70°C for biochemical analysis.

Hepatopancreas was homogenized with 0.5 mL of 35 l saline solution and muscle with 5 mL of 10% trichloroacetic acid (TCA) with a mechanical homogenizer (Vir-Tis). Protein was determined after digestion with 0.1 N NaOH (hepatopancreas) and 5N NaOH (muscle) (Bradford 1976) and total carbohydrates by the anthrone method (Roe 1955). In hepatopancreas, total lipids were determined by the sulphophosphovanillin method (Barnes & Blackstock 1973). In muscle, glycogen was extracted with absolute ethanol and the anthrone method (Van Handel 1965). Levels of all fractions are reported as $\text{mg}\cdot\text{g}^{-1}$ of tissue (wet weight). The water content in hepatopancreas was $69\% \pm 4\%$ (sd) and in muscle $76\% \pm 3\%$ (sd) ($n = 50$).

STATISTICAL ANALYSES

At the beginning of the assay, statistical differences in shell length and wet body weight among replicates were not detected ($P < 0.05$). At 60 and 120 days, two-way ANOVA was performed to assess significant differences in growth variables and in biochemical composition of hepatopancreas and muscle, using temperature regimen (normal year or El Niño) and diet (*M. pyrifera* or *E. arborea*) as independent variables (Sokal & Rohlf 1995). Mean comparisons were done by Tukey test only when there was a significant effect of the interactions ($P < 0.05$). Statistical analysis was done with STATISTICA 6.0 software.

RESULTS

Growth

Shell length (SL) and wet body weight (BW) growth ($P < 0.01$) was greater in juveniles fed *M. pyrifera* than juveniles fed *E. arborea*, regardless of temperature regimen. Nevertheless, both SL and BW growth were affected by diet in relation to the temperature

Figure 1. a. Monthly average seawater surface temperature in Bahía Asunción, measured from 1992 to 1996 and during El Niño 1997 to 1998. b. Daily average seawater temperature simulated in laboratory aquaria to represent a normal year and an El Niño year (1997 to 1998).

regimen (interaction: $P < 0.05$). At the end of the study period, the greatest mean SL and BW ($34.94 \text{ mm} \pm 0.60$, sd and $4.61 \text{ g} \pm 0.24$, sd) occurred in juveniles under El Niño-*M. pyrifera* treatment, whereas the least mean ($30.12 \text{ mm} \pm 0.91$, sd and $2.83 \text{ g} \pm 0.33$, sd) was observed in juveniles fed *E. arborea* under El Niño-*E. arborea* treatment (Fig. 2a, 2b).

Daily growth rate of SL and BW (main effect: $P < 0.01$) were higher in juveniles fed *M. pyrifera* than juveniles fed *E. arborea*, regardless of temperature regimen, although they were affected by diet in relation to the temperature regimen (interaction: $P < 0.05$). The highest daily growth rates of SL and BW ($39 \mu\text{m}\cdot\text{day}^{-1} \pm 3$ and $16 \text{ mg}\cdot\text{day}^{-1} \pm 1$) occurred in juveniles under El Niño-*M. pyrifera* treatment, and were statistically different from juveniles fed *E. arborea*; Normal-*E. arborea*, or El Niño-*E. arborea*. The lowest daily growth rates ($11 \mu\text{m}\cdot\text{day}^{-1} \pm 3$ and $4 \text{ mg}\cdot\text{day}^{-1} \pm 1$) was in juveniles fed *E. arborea* under El Niño-*E. arborea*, and were statistically different from juveniles fed *M. pyrifera*; Normal-*M. pyrifera*, and El Niño-*M. pyrifera* (Fig. 3a, 3b). The mean percent (\pm sd) of survival was $96\% \pm 4\%$ in Normal-*M. pyrifera*, $95\% \pm 5\%$ in El Niño-*M. pyrifera*, $94\% \pm 6\%$ in Normal-*E. arborea*, and $93\% \pm 2\%$ in El Niño-*E. arborea*, without significant differences between treatments (not shown).

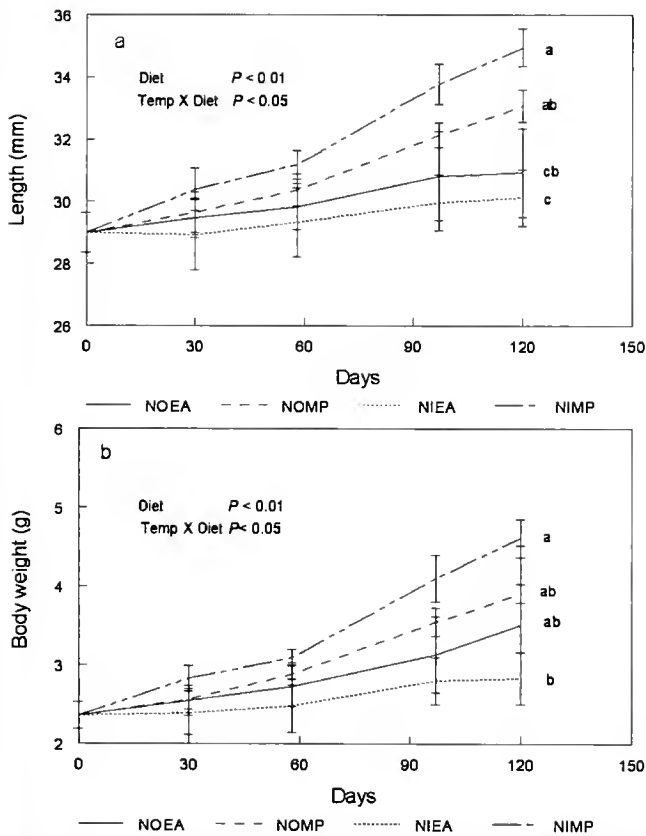

Figure 2. Mean \pm SD for triplicate groups of $n \leq 26$ of: (a) shell length and (b) body weight of juvenile green abalone *H. fulgens*. To each date, the results of bifactorial ANOVA are inserted in the figure. Factors considered for the analysis were temperature regimen (NO = normal or NI = El Niño) and diet (MP = *M. pyrifera* or EA = *E. arborea*). The main effects and interactions are shown only when significant. Mean comparisons were done by Tukey test only when there was a significant effect of the interactions. Lines not sharing the same letter are significantly different ($P < 0.05$).

Figure 3. Mean \pm SD for triplicate groups of $n \leq 26$ for daily growth in: (a) shell length and for (b) body weight in triplicate groups of juvenile green abalone *H. fulgens*. See Figure 2 for statistical analysis.

Biochemical Variables

Hepatopancreas

At maximum temperature (60 days), the protein levels of juveniles within the El Niño pattern (global mean, 121.8 mg/g) were

higher than within the normal pattern (global mean, 99.6 mg/g) (main effect: $P < 0.01$), regardless of diet. At 120 days, juveniles fed *M. pyrifera* had higher levels of protein (global means, 107.2 mg/g vs. 88.7 mg/g) (main effect: $P < 0.05$), regardless of temperature regimen (Fig. 4a). During the assay, no significant difference was observed in carbohydrate levels in relation to temperature or diet (Fig. 4b). At 60 days, no significant effect in lipid levels in relation to temperature or diet was observed. At 120

days, juveniles within the Normal pattern had higher levels of lipids (global means, 9.6 mg/g vs. 6.2 mg/g) (main effect: $P < 0.01$), regardless of diet. Juveniles fed *M. pyrifera* had higher levels of lipids (global means, 10.3 mg/g vs. 5.5 mg/g) (main effect: $P < 0.01$), regardless of temperature regimen (Fig. 4c).

Muscle

At 60 days, no significant differences were observed in protein levels in relation to temperature or diet, but at 120 days, increased levels of protein (main effect: $P < 0.01$) were present in juveniles within the El Niño pattern (global means, 164.1 mg/g vs. 141.1 mg/g), regardless of diet. Juveniles fed *M. pyrifera* had higher levels of protein (158.8 mg/g vs. 146.4 mg/g) (main effect: $P < 0.05$), regardless of temperature regimen (Fig. 5a). For carbohydrates at 60 days, no significant effect was observed in relation to temperature or diet. At 120 days, increased levels of carbohydrates (main effect: $P < 0.01$) were present in juveniles within the El Niño pattern (4.6 mg/g vs. 2.9 mg/g), regardless of diet. Juveniles fed *M. pyrifera* had higher levels of carbohydrates (4.5 mg/g vs. 3.0 mg/g) (main effect: $P < 0.05$), regardless of temperature regimen (Fig. 5b). At 60 days, glycogen levels of juveniles within the El Niño pattern (1.9 mg/g) were higher than within the Normal pattern (1.3 mg/g) (main effect: $P < 0.05$), regardless of diet. A significant interaction between temperature regimen and food was observed for the carbohydrate glycogen in muscle, with the highest levels in juveniles fed *M. pyrifera* within the El Niño pattern (interaction: $P < 0.05$). At 120 days, increased glycogen (main effect: $P < 0.01$) was present in juveniles within the El Niño pattern (3.5 mg/g vs. 1.6 mg/g), regardless of diet. Juveniles fed *M. pyrifera* had more glycogen (3.3 mg/g) than those fed *E. arborea* (1.8 mg/g) (main effect: $P < 0.05$), regardless of temperature regimen (Fig. 5c).

DISCUSSION

Higher growth obtained in juveniles fed *M. pyrifera* within the two temperature regimes may be related to the relative dietary value of the common alga species along the coast of Baja California Sur. The dietary value of species, such as *E. arborea*, *Gelidium robustum* (Gardn.) Hollenb. & Abb., and the sea grass *Phyllospadix torreyi* Watson were inferior to that of the dominant algal species of southern California, *M. pyrifera* (Serviere-Zaragoza et al. 2001). In California mariculture, *M. pyrifera* is a valuable food for young red abalone, but relatively poor diet for green abalone (Leighton 1989). Growth rates for juveniles fed rehydrated *E. arborea* and *M. pyrifera* were in the range reported by other authors in animals fed fresh or rehydrated macroalgae. Growth rates of 12 and 16 $\mu\text{m}\cdot\text{day}^{-1}$ have been reported for juveniles fed fresh kelp, *M. pyrifera* (Viana et al. 1993, Viana et al. 1996), whereas values of 19 $\mu\text{m}\cdot\text{day}^{-1}$, and 46 $\mu\text{m}\cdot\text{day}^{-1}$, were obtained for juveniles fed rehydrated *E. arborea* and *M. pyrifera*, respectively (Serviere-Zaragoza et al. 2001). Difference in rates of growth among juveniles fed the same diet in different studies may be related to differences in the chemical composition of the algae used in each assay.

Biochemical composition of tissues is affected by macroalgal diets. Although most elements of the diet are nutritionally important for growth, including carbohydrate and protein components, lipid class and content may be especially vital to abalone nutrition (Nelson et al. 2002a). Foot muscle and hepatic and gonadal tissue serve as storage depots for carbohydrates and lipids, respectively (Mercer et al. 1993). In our study, juveniles fed *M. pyrifera* had

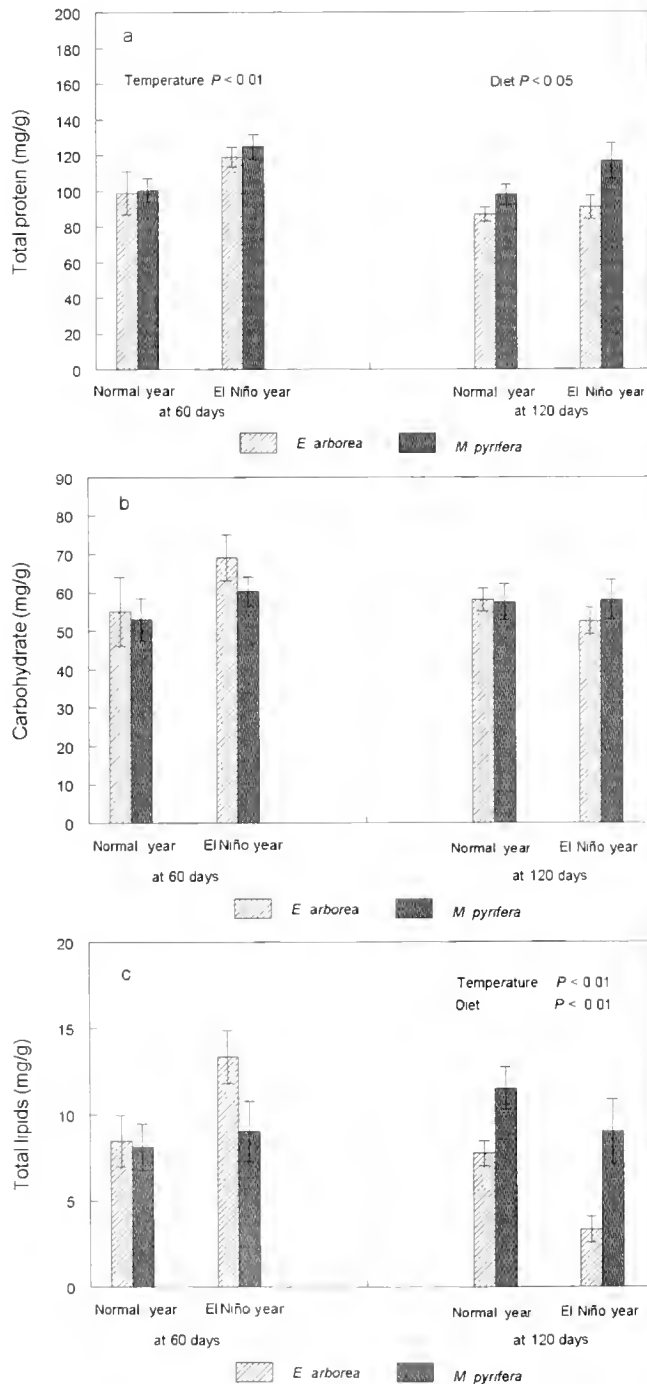

Figure 4. Mean \pm SE of hepatopancreas levels ($\text{mg}\cdot\text{g}^{-1}$ hepatopancreas tissue wet weight) of total protein (a), carbohydrate (b), and total lipids (c) in juvenile green abalone *H. fulgens*. See Figure 2 for statistical analysis at 60 and 120 days.

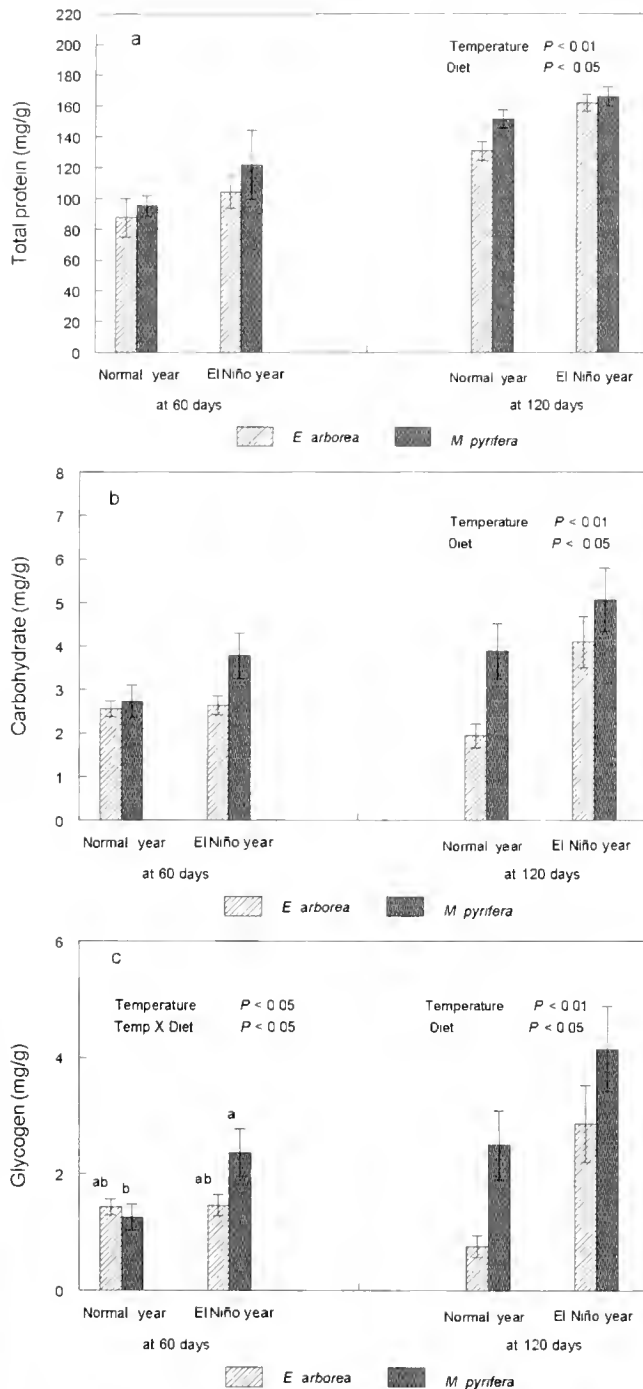

Figure 5. Mean \pm SE of muscle levels ($\text{mg}\cdot\text{g}^{-1}$ shell muscle tissue wet weight) of total protein (a), carbohydrate (b), and glycogen (c) in juvenile green abalone *H. fulgens*. See Figure 2 for statistical analysis at 60 and 120 days.

higher levels of all components in muscle than juveniles fed *E. arborea* in both temperature regimens. Muscle protein was, by far, the major component and its higher levels reflect muscle growth in accordance with the high overall growth observed in juveniles fed *M. pyrifera*. Polysaccharides stored in the foot muscle may be mainly glycogen as in many gastropods including abalone *H. discus hannai* Ino, 1953 and *H. tuberculata* Linnaeus, 1758 (Mercer et al. 1993). At the end of the assay, higher lipid levels in the

hepatopancreas of juveniles fed *M. pyrifera* were obtained, regardless of temperature. Macroalgae have lipid profiles that differ between taxa, and vary geographically and seasonally (Nelson et al. 2002b). In Baja California Sur, *E. arborea* and *M. pyrifera* have low lipid levels, ranging from 0.4% to 1.0%, without significant differences (Serviere-Zaragoza et al. 2002). Nevertheless, according to Mercer et al. (1993), lipid levels in the viscera reflect the combination of lipid levels in the diet and their bioavailability to the animals in addition to possible lipid synthesis by the abalone. This suggests differences in lipid bioavailability for these macroalgae to juvenile *H. fulgens*. Nelson et al. (2002a) found that diet and temperature influenced seasonal changes in lipid profiles, where diet most strongly affects body mass and temperature to shell length.

High survival observed in the assay ($\sim 90\%$) suggests that the maximum temperatures reached during El Niño 1997 to 1998 did not directly cause mortality in coastal juvenile green abalone populations. In culture, juvenile green abalone is tolerant of extremes in water temperature, and shows the best growth at 20°C to 28°C (Leighton 1974, Leighton et al. 1981). Low temperature reduces growth, at least in part, by affecting feeding rates and feeding duration (Uki 1981). In natural populations, high variability in size in green abalone (Guzmán del Próo et al. 2003) and reduction of growth rate in red abalone (Haaker et al. 1998) were reported during El Niños, suggesting variations in growth rate from changes in environmental conditions. This will be discussed later because it may also reflect low availability of food. In California, Friedman et al. (1997) and others suggested that high temperatures during El Niños may increase mortality of black abalone affected by the withering syndrome bacterial agent.

At the end of the experiment, hepatopancreas of juveniles within the El Niño pattern had lower levels of lipids than juveniles within the Normal pattern, regardless of diet. This suggests that during an El Niño, juveniles may use more lipid reserves than during normal years, which may in turn affect development. For macroalgae, Nelson et al. (2002b) reported that temperature induced changes in specific fatty acids, especially polyunsaturated eicosopentaenoic fatty acids, which may be important factors in gonadogenesis, and consequently, affect larval production and recruitment.

In this study, the best growth was obtained under the El Niño regimen (20°C to 28°C), providing abalone was fed *M. pyrifera*. The combined effect of high temperature and optimal food must be discussed together, because better growth was associated with higher levels of protein, carbohydrates, and glycogen in muscle. However, southern nutrient-poor water accompanies El Niño events, causing local or large-scale disappearance of the *M. pyrifera* kelp forests (North 1971, Gerard 1984, Hernández-Carmona et al. 2001). Our results suggest that higher temperatures associated with El Niño events may promote the growth of green abalone, but only if the phenomenon is not sufficiently strong to cause widespread destruction of *M. pyrifera* and other temperature-sensitive macroalgae. If El Niño events are too severe, abalone lose a main food source in Baja California Sur and must shift to other inferior algae, resulting in lower growth rates. In southern Baja California in September 1997, water temperature was high (25.3°C, anomaly + 5.7°C) and nutrients were presumably low ($<1 \mu\text{M}$), causing large-scale disappearances of all kelp forests at the southern end of their distribution (Hernández-Carmona et al. 2001). The effects of high temperatures in the Pacific waters of the Baja California Peninsula during El Niño years have been evident

in *M. pyrifera* harvests recorded in 1958, 1983, and 1998 (Casas-Valdez et al. 2003). During El Niño 1997 to 1998, *E. arborea* populations did not disappear, but its biochemical composition changed with the increase in temperature. In *E. arborea*, tissue nitrogen content decreased from 1.95% to 0.88% between July 1997 and October 1998 monitored at Isla Asunción, in Baja California (Hernández-Carmona et al. 2001).

Although the collapse of abalone populations has been ascribed to overfishing (Prince & Guzmán del Prío 1993, Shepherd et al. 1998), impacts of El Niño events on kelp forest communities suggest that these periodic environmental influences also have contributed to these declines (Lluch-Cota et al. 1999, Guzmán del Prío et al. 2003). In this study, high temperatures (simulating El Niño) enhance growth and associated biochemical indices, if optimal food availability is maintained. Data suggest that algal species, as the main diet, may be a more important factor controlling

abalone growth than temperature or the interaction between them. The effects of climate-ocean extremes, like El Niño and La Niña conditions, should be incorporated into our understanding of changes in abalone stocks, related to each species, and its age class. Further laboratory studies will be useful to increasing our understanding of the ecologic values of these influences.

UTILIZATION OF FERMENTED SKIPJACK TUNA VISCERA AS A DIETARY PROTEIN SOURCE REPLACING FISH MEAL OR SOYBEAN MEAL FOR JUVENILE ABALONE *HALIOTIS DISCUS HANNAI*

SANG-MIN LEE,^{1,*} KYOUNG-DUCK KIM² AND TAE JIN KIM³

¹Faculty of Marine Bioscience and Technology, Kangnung National University, Gangneung 210-702, Korea; ²National Fisheries Research and Development Institute, Busan 619-900, Korea ³Korean Association of Sliced Raw Fish, Busan 613-812, Korea

ABSTRACT This study was carried out to evaluate the usefulness of fermented skipjack tuna viscera (FSTV) in the diet for juvenile abalone *Haliotis discus hannai*. *Lactobacillus bulgaricus* was used for fermentation of skipjack tuna viscera. Eight isonitrogenous (about 30% crude protein) diets were formulated to include different levels (0%, 10%, 20%, and 30%) of FSTV as a replacement for either fish meal or soybean meal in diets. Three replicate groups of abalone were fed the experimental diets for 7 wk. The inclusion of FSTV up to 30% in fish meal-based diet had no significant effect on survival, body weight, shell growth, and proximate composition of abalone ($P > 0.05$). Weight gain of abalone fed the diet substituting 10% FSTV for soybean meal, was not significantly different to that of abalone fed the control diet, however this value decreased in abalone fed the 20% and 30% FSTV ($P < 0.05$). The contents of crude protein and lipid of soft body in abalone fed soybean meal-based diets were significantly affected by dietary FSTV level ($P < 0.05$). The results of this study indicate that FSTV can be used as a partial substitute protein source for fish meal or soybean meal in the formulated diet for juvenile abalone.

KEY WORDS: fermented skipjack tuna viscera, *Haliotis discus hannai*, protein source

INTRODUCTION

Abalone has a high market demand in Korea. The culture of abalone relies heavily on marine macroalgae such as *Undaria* or *Laminaria*, however, this is a problem for several reasons: unstable supply of macroalgae and increased storage cost. In addition, it has been reported that growth of abalone fed the macroalgae was lower than that of abalone fed the formulated diets (Hahn 1989, Viana et al. 1993). The better growth of abalone fed the formulated diets was attributed to the good protein quality of artificial feeds (Viana et al. 1993). In feed formulation, protein source among the dietary ingredients is very important because it is more expensive than other energy sources. Furthermore, the growth of the animal could be easily influenced by availability of dietary protein sources. Thus, high-quality proteins are necessary for a good abalone feed. Fish meal, soybean meal, and casein are the most commonly used for protein sources in abalone diets (Fleming et al. 1996). Uki et al. (1985) reported that casein was the best protein source for the diet of *Haliotis discus hannai*. But the best quality protein sources including casein are expensive. Therefore, low-cost practical alternate protein sources in diets could be of considerable economic advantage. Recently, Lee et al. (1998) suggested that the cost of *H. discus hannai* feed production could be reduced by using low cost dietary protein sources such as fish meal and soybean meal.

The utilization of waste by-products from commercial fish processing as a feed ingredient for aquaculture will be able to decrease production cost and minimize environmental pollution. Silage has proved to be a good dietary protein source for fish (Raa & Gildberg 1982). Fish silage is generally a product of high value presenting practically the similar composition as the original raw material. Previous study (Lee et al. 1998) reported that each of casein, fish meal, and soybean meal was equally good protein source for *H. discus hannai*. This study is carried out to evaluate

the utilization of fermented skipjack tuna viscera as a protein source in the diets for juvenile *H. discus hannai*.

MATERIALS AND METHODS

Preparation of Fermented Silage

The viscera of skipjack tuna (*Katsuwonus pelamis*), which was obtained from Dongwon Industry Co. (Changwon Korea), was ground and mixed thoroughly with sugar beet molasses (100 g/kg) and *Lactobacillus bulgaricus* KCTC 3188 (50 g/kg) as starter and then fermented at 35°C for 10 days in a sealed 50-L plastic bucket. After 10 days, the fermented sample was filtered by using gauzes and used for the dietary ingredient.

Experimental Diets

Two sets of experimental diets were formulated using fermented skipjack tuna viscera (FSTV) at 0%, 10%, 20%, and 30% levels replacing mainly fish meal in experiment 1 (Table 1) and soybean meal in experiment 2 (Table 2), respectively. Wheat flour and α -potato starch were used as carbohydrate, and squid liver oil was used as lipid source. Procedures for feed preparation were adapted from the method of Mai et al. (1995a). Experimental diets were dried at room temperature and stored at -25°C until used. All diets were similar in contents of crude protein (28.4% to 30.0%) and lipid (4.3% to 6.8%), which are considered to be sufficient to maintain optimum growth for *H. discus hannai* (Mai et al. 1995a, Mai et al. 1995b).

Experimental Design

Two feeding trials with completely randomized block designs were conducted to evaluate the usefulness of FSTV in the diet for juvenile *H. discus hannai* in flow-out system. Juvenile abalone were acclimated to the experimental condition for 2 wk while

being fed a commercial abalone diet containing 30% protein and 5% lipid. They were randomly stocked into twenty-four 20-L tanks at a density of 100 abalone in each tank. Three replicate groups of abalone (mean weight 848 mg and 821 mg in experimental 1 and 2, respectively) were fed *ad libitum* at intervals of 2 days for 7 wk. Before feeding, uneaten diets in each tank were cleaned by siphoning off. Filtrated seawater was supplied at a flow rate of approximately 3 L/min in each tank. Photoperiod was left at the natural condition, and mean temperature was 22 \pm 0.9 °C during the feeding trial. Abalone in each tank were collectively weighed on the days of initiation and termination at the feeding trial after being fasted for 24 h. Two-hundred abalone samples at the beginning and all abalone at the end of feeding trial were sacrificed and stored at -70 °C for chemical analysis.

Chemical Analysis

Crude protein content was determined by Kjeldahl method using Auto Kjeldahl System (Buchi B-324/435/412, Switzerland),

crude lipid content by ether-extraction method, moisture content by a dry oven (105 °C for 12 h), crude fiber content by an automatic analyzer (Fibertec, Tecator, Hoganas, Sweden), and ash content by a furnace muffler (550 °C for 4 h). Amino acids content was determined using automatic amino acid analyzer (Hitachi 835, Japan). Tryptophan was determined according to the method of Hugli and Moore (1972). Volatile basic nitrogen was measured using Conway's microdiffusion method (Conway 1950). Lipid for fatty acids analyses was extracted by mixture of chloroform and methanol (2:1, v/v) according to the method of Folch et al. (1957). Fatty acid methyl esters were prepared by transesterification with 14% BF₃-MeOH (Sigma, St. Louis, USA), and were analyzed by using a gas chromatography (HP 5890, Hewlett-Packard, USA) with flame ionization detector, equipped with HP20M capillary column (0.25 μ m \times 30 m). Injector and detector temperatures were 250 °C and 270 °C, respectively. The column temperature was programmed from 150 °C to 230 °C at a rate of 2 °C/min. Helium was used as the carrier gas. Fatty acids were identified by comparison with known standards.

Statistical Analysis

The data were subjected to one-way analysis of variance (ANOVA) using the SPSS program version 7.5 (SPSS Inc., Michigan Avenue, Chicago, Illinois, USA). Significant differences ($P < 0.05$) among mean were determined by Duncan's multiple range test (Duncan 1955).

RESULTS AND DISCUSSION

Proximate composition and volatile basic nitrogen content of the raw skipjack tuna viscera (RSTV) and fermented skipjack tuna viscera (FSTV) are shown in Table 3. The FSTV resulted in increase of carbohydrate and volatile basic nitrogen, and decrease in the contents of protein and lipid. Increase of carbohydrate in the FSTV probably originated from molasses used. The total amino acids composition (Table 4) of FSTV was similar to that of RSTV. The contents of Glu, Leu, Asp, Gly, and Ala were high among amino acids in both RSTV and FSTV. The contents of free amino acid in the FSTV were higher than those of RSTV. Considerably increased free amino acids content in the FSTV may be the result from that of the protein of RSTV, which is broken down into smaller units during storage for fermenting. Fatty acid compositions of the RSTV and FSTV are shown in Table 5, 16:0, 18:1n-9, and 22:6n-3 were most abundant fatty acids in RSTV and FSTV. The polyenes in FSTV were higher than those of RSTV. Considering compositions of amino acid and fatty acid (Mai et al. 1995b, Mai et al. 1996) in the FSTV, this fermented silage has a good nutritional condition for dietary ingredient of *H. discus hamai*.

Growth performance of *H. discus hamai* fed the diets replacing fish meal with different FSTV level is presented in Table 6 (experiment 1). In the present study, the inclusion of FSTV up to 30%

of the fish meal-based diet had no significant effect on survival, body weight, and shell growth of abalone ($P > 0.05$). When *H. discus hamai* fed the diets replacing soybean meal with different FSTV level (Table 6, experiment 2), weight gain of abalone fed the diet containing 10% FSTV was not significantly different to that of abalone fed the control diet, however this value decreased in abalone fed the 20% and 30% FSTV ($P < 0.05$).

The feeding value of the dietary protein source depends not only on the quantity of nutrient such as protein and essential amino acids, but also on the ability of the fish to use that nutrient (National Research Council 1993). Additionally, various characteristics of the feedstuff including nutritional values, cost, stable supply, and palatability should be considered to commercially use as the protein source in practical diet. Viana et al. (1993) reported that fish meal was a good dietary protein source for the growth of *H. fulgens*. The development of commercial feeds for aquaculture has been traditionally based on fish meal as the main protein source due to its high protein content and balanced essential amino acid profile. However, because of high price of good quality proteins including fish meal, many studies have been focused on alternative practical protein sources which have economic advantages for aquaculture (Viana et al. 1996, Lee et al. 1998, Mukhopadhyay & Ray 1999, Giri et al. 2000, Middleton et al. 2001). Fish silage has a good potential as a protein source for some fish feed (Hardy et al. 1983, Espe et al. 1992, Fagbenro et al. 1994, Fagbenro & Jauncey 1995). The results obtained from this study suggest that *H. discus hamai* maybe use the protein from FSTV and fish meal with similar efficiency. This is agreement with other studies (Fagbenro 1994, Vidotti et al. 2002). Fagbenro et al. (1994) reported that up to 75% of fish meal protein was successfully replaced by blended lactic acid fermented fish silage:soybean meal (1:1) incorporated in diets fed to Nile tilapia fingerlings.

Weight gains (406–575 mg/abalone) of *H. discus hamai* fed the soybean meal-based diets (experiment 2) were higher than those (279–323 mg/abalone) of abalone fed the fish meal-based

Values (mean ± S.E. of three replications) in the same row not sharing a common superscript are significantly different ($P < 0.05$).

diets (experiment 1), regardless of different FSTV levels. This result suggests that soybean meal is very good protein source in diet for growth of *H. discus hannai*. However, Uki et al. (1985) reported that growth of *H. discus hannai* fed the casein diet was higher than that of abalone fed the diet containing fish meal or soybean meal. On the other hand, Lee et al. (1998) reported that each of casein, fish meal, and soybean meal was equally good protein source for *H. discus hannai*. The different growth responses to dietary protein sources among studies are probably due to feeding and abalone conditions, such as water temperature, abalone size, and dietary composition used in their studies.

There were no significant differences ($P > 0.05$) in moisture, protein, lipid, and ash contents of soft body in *H. discus hannai* fed

the diets replacing fish meal with different FSTV level (Table 7, experiment 1). When *H. discus hannai* fed the diets replacing soybean meal with different FSTV level (Table 7, experiment 2), crude protein content of soft body was higher in abalone fed control diet, while crude lipid content in abalone fed the diet containing 30% FSTV was lower than that of in the others ($P < 0.05$).

The results obtained from this study indicate that FSTV has a good potential as a substitute protein source, especially for fish meal in the formulated diet for juvenile *H. discus hannai*. The use of FSTV as an ingredient in diet for *H. discus hannai* could result in cheaper artificial feeds, making its culture more economically viable, and use of tuna viscera is potentially a profitable solution to a waste problem of the canned tuna industries.

ABSTRACT A 152-day feeding trial was conducted in a recirculating water system to investigate the effects of vitamins A (retinol) and D (cholecalciferol) on shell biomineralization of the abalone *Haliotis discus hannai* Ino. Triplicate groups of juvenile abalone (initial weight: 0.35 ± 0.03 g; initial shell length: 11.31 ± 0.25 mm) were fed to satiation daily with one of the 16 semipurified diets containing 0 , 1×10^3 , 1×10^5 , 1×10^6 IU/kg vitamin A and 0 , 500 , 1×10^3 , 5×10^3 IU/kg vitamin D in a 4×4 factorial design. The results showed that vitamin D significantly increased the ratio of calcite/aragonite in the shell, in the case of deficient (0 IU/kg) or excessive (1×10^6 IU/kg) dietary vitamin A supplementation. When dietary vitamin A supplementation ranged from 1×10^3 to 1×10^5 IU/kg, vitamin D significantly decreased the ratio of calcite/aragonite in the shell. The concentrations of Mg, Zn, and Sr in the shell were independent of the supplementation of these two vitamins. Meanwhile, the contents of Ca, P, and Cu in abalone shell increased with supplementation of the vitamins A and D, and significant interaction between vitamin A and D was observed on the concentrations of both Ca and Cu in shell. Vitamin A, instead of vitamin D, significantly increased Fe concentration in shell. Trends of the ratio of acidic/basic amino acids [(Asx + Glx)/(Lys + Arg + His)] in the shell soluble matrix protein (SMP) changing with dietary vitamin A and D were in agreement with those of the ratio of calcite/aragonite in the shell. The two vitamins did not change the shell ultrastructure as shown by scanning electron microscopy (SEM) and components of SMP expressed by SDS-PAGE.

KEY WORDS: *Haliotis discus hannai*, vitamin A, vitamin D, shell, biomineralization

INTRODUCTION

Vitamin A (retinol) is sequentially metabolized to retinaldehyde, retinoic acid for its functions in animals (Hofman & Eichele 1994, Saari 1994). All-*trans*-retinoic acid (ATRA) acts through a series of receptors, termed retinoic acid receptors (RAR) α , β , and γ . Meanwhile, 9-*cis*-retinoic acid (9-*cis*-RA) can bind another series of retinoid receptors, termed retinoid X receptors (RXR), and initiate transcription of RXR responsive genes in a ligand-dependent fashion (Rohde et al. 1999). Vitamin A is functionally related to vision, reproduction, and specific immune responses (Sporn & Roberts 1984, Dhur et al. 1991, Thompson et al. 1994). Furthermore, it induces the expression of genes associated with the terminal mineralization phase of chondrocyte maturation and promotes apatite deposition in the extracellular matrix (Iwamoto et al. 1993).

Vitamin D (cholecalciferol) requires two hydroxylations to be converted into its active hormonal form, $1\alpha,25$ -dihydroxyvitamin D₃ [$1\alpha,25(\text{OH})_2\text{D}_3$]. It is activated by hydroxylation first in the liver to form 25-hydroxyvitamin D₃ [$25(\text{OH})\text{D}_3$], and then in the kidney to form $1\alpha,25(\text{OH})_2\text{D}_3$ (Henry & Norman 1984, Norman & Henry 1993). $1\alpha,25(\text{OH})_2\text{D}_3$ exerts its functions through 2 pathways: nongenomic pathway (reviewed in Revelli et al. 1998) and genomic pathway (reviewed in Jones et al. 1998). The genomic pathway requires binding of $1\alpha,25(\text{OH})_2\text{D}_3$ to the nuclear vitamin D receptor (VDR), heterodimerization with a retinoid X receptor (RXR), and interaction with specific vitamin D-responsive element (VDRE) consensus sequences of target genes (Colnot et al. 1995, Haussler et al., 1998). Vitamin D plays an important role in calcium and phosphate homeostasis (DeLuca & Schnoes 1976). Recent studies have shown that vitamin D regulates the gene expression of proteins involved in the formation of mineralized tissues. $1\alpha,25(\text{OH})_2\text{D}_3$ stimulates the expression of osteocalcin, which is a

small extracellular bone matrix protein with a capacity for specific Gla (γ -carboxyglutamic acid)-dependent binding of Ca^{2+} (Mahonen et al. 1990). Such function of $1\alpha,25(\text{OH})_2\text{D}_3$ was further demonstrated by later studies (Luegmayer et al. 1998). In addition, $1\alpha,25(\text{OH})_2\text{D}_3$ was found to be able to regulate the expression of a tooth-specific gene: amelogenin gene (Papagerakis et al. 1999). Amelogenins are the major (90%) matrix proteins for forming enamel (Sasaki & Shimokawa, 1995). Amelogenesis is a multi-stage process that generates a fully mineralized layer of enamel on the crowns of teeth (Smith & Nanci 1995). This process is controlled by ameloblasts, which secrete an extracellular protein matrix and provide a gel scaffold to support apatitic crystal growth (Fincham & Simmer 1997).

In contrast to bone and tooth, mollusc shell is mostly composed of calcium carbonate (CaCO_3) (95% to 99% in weight), which is usually in the crystallographic form of calcite or (and) aragonite (Currey 1999). The shell contains a small amount of protein and polysaccharide (1% to 5% in weight). The organic material is responsible for the fracture toughness of the shell, which is 3000 times greater than pure crystalline aragonite (Weiner 1986). The organic matrix is also involved in the crystallization process: some parts may enhance, others may inhibit the crystal formation of calcium carbonate (Belcher et al. 1996, Weiss et al. 2000). It has been demonstrated that the soluble matrix proteins (SMP) play an important role in the control of crystal polymorphism phase switching and orientation (Belcher et al. 1996, Falini et al. 1996).

Shell biomineralization can be influenced by factors such as environmental (Kennedy et al. 1969, Almeida et al. 1998) and also the metabolic state of the organism (Wilkes & Crenshaw 1979). It was demonstrated in our previous studies that dietary Zn and P changed the character of mineralogy and the pattern of SMP in the shell of the abalone *Haliotis discus hannai* Ino (Zhang et al. 2002, Mai et al. 2003). Either vitamin A or D plays an important role in mineralization of bone and tooth as described earlier. There is no information available on the effects of vitamin A and D on mollusc shell biomineralization. There is potential for interaction between

*Corresponding author. Fax: +86-532-2032495; E-mail: kmaj@ouc.edu.cn

vitamin A and D signaling pathways, because RXR is needed for the two vitamins to exert their functions (Glass 1994, Carlberg 1995). Furthermore, such interaction influences bone mineralization in the rat (Rohde et al. 1999) and the performances of growth and metabolism in *H. discus hannai* (Zhang et al., unpublished data). The aim of this study is to investigate whether vitamin A and D have effects on shell biomineralization in *H. discus hannai*.

MATERIALS AND METHODS

Animals, Diets and Experimental Treatments

Abalone juveniles (initial weight: 0.35 ± 0.03 g; initial shell length: 11.31 ± 0.25 mm) used in this experiment were derived from a spawning at Huaxin Fisheries Co., Shandong, China.

Diets were formulated with purified ingredients. The composition and the proximate analysis of the diets are presented in Table 1. The basal diet contained 32.8 IU vitamin A/kg diet and 25.6 IU vitamin D/kg diet, analyzed by high-performance liquid chromatography (HPLC). Experimental diets with 4 levels of vitamin A ($0, 1 \times 10^3, 1 \times 10^5$ and 1×10^6 IU/kg) and 4 levels of vitamin D ($0, 500, 1 \times 10^3$ and 5×10^3 IU/kg) were prepared by adding appropriate quantities of all-*trans*-retinol acetate and cholecalciferol to the basal diet in a 4×4 factorial arrangement.

The growth experiment was conducted in a recirculating water

system. Abalone were stocked at 30 animals for each rearing unit in a plastic basket (20 cm \times 20 cm \times 10 cm) per glass aquarium (45 cm \times 25 cm \times 35 cm). There were 16 treatments, and each treatment was conducted in three replicates. The feeding trial was run for 152 days.

Environmental Conditions of the Growth Experiment

During the 152-day growth experiment, water temperature was maintained at 18 ± 1 °C, salinity 31–35, pH 7.8–8.0. Dissolved oxygen was not less than 6 mg/L, and there were negligible levels of free ammonia and nitrite. Mineral concentrations in the seawater of the rearing system were determined by inductively coupled plasma-atomic emission spectrophotometer (ICP-OES: VISTA-MPX, VARIAN). Concentrations of Ca, P, Mg and Sr were 301.0, 0.5, 78.4 and 8.6 mg/L, and those of Cu, Zn, Fe, and Mn were 1.5, 8.2, 1.2 and 0.1 μ g/L.

Preparation of Shell Samples

At the termination of the feeding trial, animals were not fed for 3 days. All the abalone were removed from the baskets, weighted, measured and counted. Then, abalone from each replicate were immediately frozen (-70 °C). Shells were separated from the soft body, and then were cleaned under tap water to remove residual dirt. Subsequently, shells were kept in 5% NaOH for 7 h. After being washed completely with deionized water, the samples were air-dried for 24 h for the following analyses.

Scanning Electron Microscopy

To examine variation in crystalline ultrastructure, shells of abalone fed the diets with different levels of vitamin A and D were analyzed by SEM. Vertical sections of shells for SEM were prepared by fracturing. SEM was carried out on a JEOL JSM-840 instrument.

Mineralogy and Chemical Compositions

Mineralogical composition of the shells was investigated by x-ray diffractometry on powdered samples (Cohen & Branch 1992). The fraction of each type of crystal (aragonite, calcite, and dolomite) was expressed as a percentage.

Concentrations of Ca, P, Mg, Fe, Zn, Cu, and Sr in shells were determined by ICP-OES. Preparation of the shells was according to the method of Carriker et al. (1980).

Isolation and Purification of the Soluble Matrix Protein

The cleaned shells were crushed into a fine powder, then suspended in 3,500 molecular weight cutoff dialysis membranes (Cole-Parmer Instrument Co., USA) and dialyzed against 5% acetic acid containing 0.01% (w/v) sodium azide for 72 h at room temperature. This was followed by exhaustive dialysis against ultra-pure water for 48 h to remove the acetic acid. The resultant dialysate was centrifuged at $\times 10,000g$ for 30 min at 4°C. The supernatant containing protein SMP was collected and lyophilized for further analyses.

Vertical Polyacrylamide Gel Electrophoresis

Analysis of SMP was performed using the discontinuous buffer system. Electrophoresis of SDS-PAGE (18% separating gel and 4% stacking gel) was prepared with acrylamide:biacrylamide and run in Mini-PROTEAN II equipment (Bio-Rad, Hercules, CA).

USA). Samples (20 μ L) were added to wells (1-cm high). All the stock solutions were prepared by the methods described in the instruction manual (Bio-Rad, Hercules, CA, USA). Gel thickness was established with 1-mm spacers. Molecular weight (MW) marker was obtained from Bio-Rad (catalog number 161-0304). Other electrophoretic chemicals were from Amersham-Pharmacia (New Territories, Hong Kong, People's Republic of China). Procedures were carried out at room temperature. The power condition was 150 V, constant voltage setting. The usual run time was approximately 90 min. The method in combination with silver nitrate and stains-all (4,5,4',5'-dibenzo-3,3'-diethyl-9-methylthiocarbocyanine bromide), in the present study, was accepted to stain the gels (Goldberg & Warner 1997).

Amino Acids Analyses

To have enough samples for amino acid analyses, SMP from the 3 replicates in a treatment were pooled together. Sample (1 mg) of SMP was hydrolyzed *in vacuo* using 6N HCl for 24 h at 110°C and derivitized with dabsyl chloride (Kamp 1990). Analyses of derivitized amino acids were performed by reversed-phase HPLC (RP-HPLC) on an ODS (octadecylsilane) Hypersil column (HP; 250 \times 4 mm; 5 μ m). Eluant gradients with two solvent buffers were formed. The amount of acetonitrile (A) was gradually increased in 25 mM sodium acetate (pH 6.5) (B). Fifteen percent A was increased to 25% in 10 min, 40% in 20 min, 70% in 10 min, and held at 70% for 5 min before returning to 15% in 5 min. Tryptophan was lost during hydrolysis, and cystine coeluted with a reagent peak during amino acid separation. Therefore, tryptophan and cystine values are not reported. Values reported as Glx included both glutamate and glutamine, because glutamine was converted to glutamate during the analysis. Values for Asx included aspartate and asparagines, because asparagine was converted to aspartate.

Statistical Analysis

All percentage data were square-root arcsine transformed prior to analysis. Data were submitted to 2-way analysis of variance using the STATISTICA™ package. When significant differences ($P < 0.05$) were found, means were compared using the Tukey's test.

RESULTS

Scanning Electron Microscopy

There are no variations in shell ultrastructure of *H. discus hannai* fed the diets with different levels of vitamin A and D. Crystals in the shell could be divided into two layers from the outer to the inner shell surface: the prismatic layer and the nacreous layer. The former was composed of calcite. The latter was composed of tabular blocks of aragonite, and aragonitic tablets resemble a brick wall (Fig. 1). Growth line was found in the shells. It was continuous through the naere (Fig. 2).

Mineralogy

Contents of aragonite, calcite, and dolomite in shell are given in Table 2. Aragonite was the dominant type of crystal. Although vitamin A significantly influenced contents of aragonite (91.90% to 96.39%) and calcite (1.72% to 5.25%), there was no obvious trend. Shell dolomite content (1.39% to 2.85%) was not significantly influenced by vitamin A.

Figure 1. Vertical fracture-plane of the shell composed of calcitic prisms (P), and the succeeding nacreous layer (N), $\times 1,600$.

In the case of hypo- or hyper-vitamin A supplement (0 or 1×10^6 IU/kg), dietary vitamin D significantly increased shell calcite content. When dietary vitamin A supplements ranged from 1×10^3 to 1×10^5 IU/kg, vitamin D significantly decreased the content of calcite in shell. There were no significant effects of vitamin D on both aragonite and dolomite contents.

Significant interaction between vitamin A and D was found on contents of aragonite and calcite in the shell. When dietary vitamin A supplements ranged from 1×10^3 to 1×10^5 IU/kg, both vitamin A and D increased shell aragonite content, but decreased shell calcite content. Such significant interaction was not found with shell dolomite content.

Chemical Composition of Shells

Concentrations of Ca, P, Mg, Fe, Zn, Cu, and Sr in shell are given in Table 3. Vitamin A had significant effects on concentrations of Ca, P, Fe, and Cu. When dietary vitamin A levels ranged from 1×10^3 to 1×10^6 IU/kg it increased shell Ca concentration regardless of the dietary vitamin D supplements. Concentrations of

Figure 2. Nacre of shell and growth line. Nacre is composed of tabular blocks of aragonite (A), and growth line (G) is a deposit of calcium, $\times 1,600$.

* C/A (%) = (calcite/aragonite) × 100.

the shell Fe in treatments with 1×10^5 and 1×10^6 IU/kg dietary vitamin A were significantly higher than those in treatments with 0 or 1×10^3 IU/kg dietary vitamin A.

Vitamin D had no significant effects on concentrations of P, Mg, Fe, Zn, and Sr in the shell. When dietary vitamin A ranged from 1×10^5 to 1×10^6 IU/kg, vitamin D significantly increased shell Ca concentration. Vitamin D significantly elevated the shell Cu concentrations at all dietary vitamin A levels.

Interaction between vitamin A and D were found significant on concentrations of Ca and Cu in shell, not on other analyzed minerals. This interaction significantly increased concentrations of Ca and Cu in shell.

SDS-PAGE

The SDS-electrophoretical separation of the SMP gave five bands (Fig. 3). The gel was somewhat overstained to help visualize minor components. Preparations of SMP from the different shells of abalone fed the diets with different levels of vitamin A and D showed a similar staining profile. Four distinct bands were found at 36.6, 30.9, 24.5, and 19.7 kDa respectively. A heavy stained region was labeled *a*.

Amino Acid Compositions

Apparent amino acid contents of the soluble matrix protein (SMP) from the shell are given in Table 4. The dominant amino acids in shells were Asx, Ser, Gly, and Phe. Meanwhile, Pro and Met were not detected in shells. Vitamin D increased the ratio of

acidic/basic amino acids [(Asx + Glx)/(Lys + Arg + His)], in the case of deficient (0 IU/kg) or excessive (1×10^6 IU/kg) dietary vitamin A supplement. When dietary vitamin A supplements ranged from 1×10^3 to 1×10^5 IU/kg, vitamin D decreased those ratios in shell.

DISCUSSION

To our best knowledge, the present study is the first report on the effects of vitamin A and D on shell biomineralization in molluscs. The results showed that various levels of the two vitamins in diets did not change the ultrastructure or the soluble matrix protein (SMP) components in the shell of *H. discus hannai*. However, mineralogical and chemical compositions in shells were significantly influenced by dietary vitamin A and D. In previous study, it was also demonstrated that mineralogical and chemical compositions were very important to investigate the effects of dietary guaiacol and Zn on shell biomineralization in *H. discus hannai* (Mai & He 2000, Mai et al. 2003). It is suggested that changes in mineralogical and chemical compositions in the shell are responsive indicators to study the relationship between nutrients and shell biomineralization in abalone.

The role of vitamin A in bone mineralization has been well established. Low doses of vitamin A induce expression of the alkaline phosphatase (AKP), osteonectin, and osteopontin genes. As a result, massive hydroxyapatite is deposited. The mechanisms by which vitamin A induces changes in mineralization-related gene expression in chondrocytes is possibly the temporal expression of nuclear retinoic acid receptor (RAR) isoforms (Iwamoto et al. 1993). Overdoses of vitamin A cause abnormalities in bone mineralization of larval flounder. These bone deformities were due to hypervitaminosis induced by excessive vitamin A that accelerated chondrocyte maturation (Dedi et al. 1995). In the present study, vitamin A significantly increased concentrations of Ca and P in the shell. Given that AKP plays an important role in metabolism of Ca and P (Norman et al. 1970, Birge & Avioli 1981), results mentioned earlier are suggested to relate to AKP activity in abalone. In our previous study, it was demonstrated that AKP activities in the viscera of abalone increased with dietary vitamin A levels (unpublished data). At present, it is difficult to identify whether vitamin A elevates expression of the AKP gene in abalone, because there are not enough direct data. Further study is needed to make the related mechanism clear.

Vitamin D can stimulate intestinal Ca and P intake and can lead to hypercalcemia and hyperphosphatemia in walking catfish *Clarias batrachus* and American eels *Anguilla rostrata* (Swarup & Srivastav 1982, Fenwick et al. 1984). Vitamin D did not significantly influence the concentrations of Ca and P in the bone of the blue tilapia *Oreochromis aureus* (O'Connell & Gatlin 1994). These findings indicate that the role of vitamin D in calcium metabolism of fish is not well established. In the present study, dietary vitamin D significantly increased concentrations of Ca and P in shell. These results are in agreement with those from a previous study (Zhou, pers. comm.). Given that AKP is involved in the metabolism of Ca and P (Norman et al. 1970, Birge & Avioli 1981), changes of AKP activity could be responsible for Ca and P concentrations in shell in the present study. It was demonstrated in our previous study that AKP activities were increased with dietary vitamin D (unpublished data). Vitamin D also elevated bone-specific AKP activity in vertebrates (Spiess et al. 1986). Combin-

TABLE 3.

Concentrations of Ca, P, Mg, Fe, Zn, Cu and Sr in the shell of *Haliotis discus hannai* fed the diets with different levels of vitamin A (A) and D (D) for 152 days

^{a-d} Means in the same column sharing a common superscript letter were not significantly different ($P > 0.05$) as determined by Tukey's test.

ing these findings, it is suggested that vitamin D, as well as vitamin A, stimulate AKP activity, subsequently increasing the deposition of Ca and P in shell of *H. discus hannai*.

It has been demonstrated that the soluble matrix proteins (SMP) play important roles in the control of CaCO₃ crystal polymorphism phase switching and orientation in the mollusc shell (Belcher et al. 1996, Falini et al. 1996). Furthermore, aragonitic and calcitic SMP determine the nucleation and growth of aragonite and calcite, respectively (Belcher et al. 1996). Kawaguchi and Watabe (1993) reported high ratios of acidic/basic amino acids (50.1) in the calcitic prismatic layer soluble matrix (SM) of the American oyster *Crassostrea virginica*. Data calculated from some other studies shows that the ratio of acidic/basic amino acids (14.9) in calcitic shell of the Antarctic scallop *Adamussium colbecki* (Halloran & Donachy 1995) was greater than that (3.4) in aragonitic shell of the freshwater snail *Biomphalaria glabrata* (Marxen & Becker 1997). In the present study, trends of the ratio of calcite/aragonite in the shell, changing with different dietary vitamin A and D, were in agreement with those of the ratio of acidic/basic amino acids [(Asx + Glx)/(Lys + Arg + His)] in SMP. In our previous study, we found that ratios of acidic/basic amino acids, as well as ratios of calcite/aragonite in the shell of *H. discus hannai*, were significantly increased with dietary zinc levels (Mai et al. 2003). Results from the present study, and previous studies on other molluscs discussed earlier, may imply that SMP from calcitic shell was more acidic than that from aragonitic shell. It is suggested that the most likely way for vitamin A and D to influence the ratio of calcite/aragonite is to change the concentrations of calcitic and aragonitic SMP in shell. It has been well established in vertebrates that the most important way for vitamin A and D to influence the mineralization of bone and tooth is to regulate the gene expression of proteins

Figure 3. Stains-all and silver staining of the soluble matrix protein (SMP) from the shell of *H. discus hannai* fed the diets with different levels of vitamin A and D after electrophoresis. Because all the SMP preparations of shell show a similar pattern of bands, here only a representative is presented. Samples (20 μ L) are loaded and electrophoresed on 18% acrylamide:bisacrylamide gels and stained with the Stains-all/silver protocol. Numbers on the left margin indicate the positions of molecular weight (MW) markers. Numbers and letter on the right margin are designations assigned to the different SMP.

^a Because the amount of SMP from one replicate was not enough for analysis of amino acid composition, SMP from 3 replicates in a treatment were pooled as one sample for RP-HPLC.

^b A/B, acidic/basic amino acids [(Asx+Glx)/(Lys+Arg+His)]; ND, not detected.

involved in the formation of these mineralized tissues (Mahonen et al. 1990, Iwamoto et al. 1993, Luegmayer et al. 1998, Papagerakis et al. 1999). It is still unclear if vitamin A and D regulate the gene expression of SMP. Further work will be necessary to better understand the relationship between the two vitamins and SMP, and to investigate the molecular mechanisms of shell biomineralization in *H. discus hannai*.

ABSTRACT The shell microstructure of the abalone, *Haliotis discus hannai* Ino, was studied using scanning electron microscopy. The shell consists of the periostracum, prismatic, and nacreous layers with calcite in the outer prismatic layer and aragonite in the inner nacreous layer. FTIR analysis of the prismatic powder showed characteristic spectra of calcite: 876 cm^{-1} (ν_2) and 710 cm^{-1} (ν_4), whereas aragonitic nacreous powder had characteristic spectra of 858 cm^{-1} (ν_2) and $712 - 700\text{ cm}^{-1}$ (ν_4). Another absorption area in the range $2520 - 2650\text{ cm}^{-1}$ in both nacreous and prismatic layers was assigned to HCO_3^- groups, residing in the mineral or at the organic mineral interface, which suggests a potential participation of HCO_3^- groups as an intermediate in shell formation. In the *in vitro* crystallization experiment, it was found that the soluble matrix from different shell layers were able to induce different crystals with special morphologies. Soluble matrix, isolated from the prismatic layer, was shown to induce globular calcite formation *in vitro*, whereas soluble matrix from the nacreous layer induced the formation of almost symmetrical, hedgehog-like, aragonitic aggregates. The regulating mechanism of the formation, morphologic development, and crystallography of minerals in abalone shell is discussed.

KEY WORDS: *Haliotis discus hannai*, shell, microstructure, mineralogy, soluble matrix, *in vitro* crystallization

INTRODUCTION

Mollusk shells are polycrystalline composites of calcium carbonate and ~1% to 5%, by weight, of proteins and glycoproteins (Kaplan 1998). The shell has a fracture strength of about 3000 times higher than that of the inorganic CaCO_3 . These properties depend on microstructural characteristic, crystal phase, grain morphology and aggregation, and also on crystallite orientation (Chateigner et al. 2000).

The underlying secret of the above phenomena is the organic matrix existing in the mollusk shells. The matrix of shells can be separated into 2 broad classes: the soluble matrix (SM) and the insoluble matrix (IM). Soluble matrix is generally acidic due to high mole fractions of Asp and Glu, which are considered to play important roles in crystal nucleation, crystal growth and inhibition, crystal polymorphism, and atomic lattice orientation (Weiner & Addadi 1991, Wheeler 1992, Falini et al. 1996, Belcher et al. 1996). On the contrary, the insoluble matrix has a relatively high proportion of nonpolar amino acids, which are believed to provide the organic matrix framework for calcium carbonate to deposit (Weiner & Traub 1980, Weiner 1986).

CaCO_3 has 3 known polymorphs: calcite, aragonite, and vaterite phases. The calcite and aragonite are stable polymorphs and observed in nature, whereas the vaterite is a metastable polymorph and rarely seen in biologic systems (Weiner & Addadi 1997). Addadi & Weiner (1985) demonstrated that the biomacromolecules from shell could exert control over the polymorphism of a particular mineral phase. Previous studies on *in vitro* crystallization have shown that soluble proteins, associated with a variety of calcium carbonate biominerals, are able to interact with calcite growth and affect a variety of crystal properties (Berman et al. 1988, Berman et al. 1993, Didymus et al. 1993, Wierzbicki et al. 1994, Aizenberg et al. 1994, Sims et al. 1995). Falini et al. (1996) showed that macromolecules extracted from the aragonite layer of mollusk shells induced nucleation of aragonite crystals under an appropriate microenvironment. Moreover, Belcher et al. (1996)

demonstrated that a 16-kDa soluble polyanionic protein is sufficient to allow the transformation from the calcite to the aragonite phase. However, the exact mechanisms by which the macromolecules control the polymorphism, in both biotic and abiotic systems, are not yet well understood.

The shells of abalone are, in some cases, exclusively calcitic (e.g., *Haliotis kamschatkana*, *Haliotis rufescens*) or aragonitic (e.g., *Haliotis asinina*, *Haliotis glabra*), but in many species the shell contains both calcite and aragonite (e.g., *Haliotis tuberculata*) (Dauphin et al. 1989). The diversity of crystal compositions in the shell of abalone presents a unique and interesting model for exploring shell biomineralization. As results on the biologic mechanisms of biomineralization have been obtained previously on the abalone *Haliotis discus hannai* Ino, it can be considered as a model to study the mineralization, using an interdisciplinary approach (Mai et al. 2003).

Until now there remains a large gap between the understanding of chemical model systems and biochemical/physiologic processes that control shell formation. The aim of this study is to investigate the inorganic part of the calcium carbonate shell of *H. discus hannai* Ino and to begin to elucidate the roles of the soluble matrix from abalone shell on the *in vitro* crystallization of calcium carbonate.

MATERIALS AND METHODS

Scanning Electron Microscopy Observation of Abalone Shell

Samples were fractured from the growing margin of abalone shell (shell length: $8.5 \pm 0.3\text{ cm}$, body weight: $75.3 \pm 3.2\text{ g}$) and mounted on a stub, vacuum-coated with gold-palladium for 5 min in a Technics gold-sputter, and scanned using a scanning electron microscopy (scanning electron microscopy, JEOL-840). Different layers of shell were subject to x-ray diffraction on a Rigaku diffractometer, which used a $\text{Cu K}\alpha$ radiation and operated at 40 KV and 100 mA, set to run from 25° to 60° at a step size of 0.01° 2θ and a counting time of 5 sec.

*Corresponding author. E-mail: kmaj@ouc.edu.cn

IR Spectrometry Analysis

All spectra were recorded at 4 cm^{-1} resolution with 64 scans with a strong Norton–Beer apodization on a Perkin–Elmer model 1600 Fourier transform IR spectrometer (FTIR), in the wavenumber range $4000 - 600\text{ cm}^{-1}$. The system was purged and permanently maintained under nitrogen to reduce atmospheric CO_2 and H_2O absorption. A background spectrum was measured for pure KBr. Sample spectra were automatically ratioed against background to minimize CO_2 and H_2O bands. All samples and KBr were dried in an oven at 38°C overnight and then ground into fine powder in an agate mortar for 10 min.

Isolation of the Soluble Matrix Proteins

The nacreous layer and prismatic shell were separated by mechanical scraping, then were crushed and pulverized into fine powder, respectively. Powders were suspended in 3,500 molecular weight cutoff dialysis membranes (Cole–Parmer Instrument, USA) and dialyzed against 5% acetic acid containing 0.01% (w/v) sodium azide for 72 h at room temperature. This was followed by exhaustive dialysis against ultrapure water for 48 h to remove the acetic acid. The resultant dialysate was centrifuged at $\times 20,000g$ for 30 min at 4°C , which separated the supernatant (SM) and precipitated (IM) fractions. The supernatant was collected and lyophilized for subsequent experiments.

Crystal Growth Experiments

CaCO_3 crystals were grown on glass coverslips in a CaCl_2 solution. Briefly, 3 mL of 12 mM CaCl_2 solution was introduced into the wells containing the coverslips. The wells were covered

with aluminum foil with punctures and placed inside a closed desiccator for 2 days for crystal growth by the slow diffusion of gases released by the decomposition of ammonium carbonate placed inside the desiccator (Rajamani et al. 2003). To study the role of soluble matrixes from nacreous and prismatic shells on CaCO_3 crystallization, aliquots of protein ($10\text{ }\mu\text{g/mL}$) were introduced into each well. After 2 days, the coverslips were carefully lifted from the crystallization vessels, rinsed gently with Millipore water, and air dried at room temperature for further analysis.

Characterization of Synthesized Crystals

The morphologies of the crystals were observed under an Olympus BH-2 phase contrast microscope (Olympus) with a digital camera (Pixera, Pro150ES). The crystals were then scraped and characterized by FTIR.

RESULTS

Shell Structure of Abalone Shell

There are 3 layers sequentially from the exterior to the interior of the abalone shell (Fig. 1). An uncalcified layer, called the periostracum, covers the shell externally. The calcified layer is composed of 2 different polymorphs of calcium carbonate: calcite and aragonite. The majority of the calcite forms the prismatic layer of the shell. The aragonite, formed between the mantle and the prismatic layer, is deposited as rounded or polygonal oriented (001) tablets. These tablets are $\sim 0.2\text{--}0.3\text{ }\mu\text{m}$ thick and $\sim 2\text{--}10\text{ }\mu\text{m}$ wide. The tablets are arranged in columns to form a stack with their c-axis aligned in the growing margin.

Figure 1. Scanning electron microscopy image of a vertical section of a fractured shell showing the shell structure of *Haliotis discus hannai* Ito. A. Three layers of the shell: nacreous layer (a), prismatic layer (b) and periostracum (c); B. the columnar structure resided in the growth margin of the shell; C. the polymorph of aragonitic tablets.

FTIR Analysis of Prismatic Powder and Nacre Powder

Figure 2 shows that both prismatic and nacreous powders were composed of organic matrix and mineral phase with numerous bands from 4000 cm^{-1} to 600 cm^{-1} . The spectra of calcite (prismatic powder) are characterized by 3 prominent absorption maxima at $1430\text{--}1450\text{ cm}^{-1}$ (ν_3), 876 cm^{-1} (ν_2) and 710 cm^{-1} (ν_4), and one minor band at $1012\text{--}1087\text{ cm}^{-1}$ (ν_1). The splitting of ν_4 , which is prevalent in the spectra of aragonite, is absent from calcite. The IR spectra of nacreous powder are characterized by 3 prominent absorption maxima at $1470\text{--}1490\text{ cm}^{-1}$ (ν_3), 858 cm^{-1} (ν_2), and $712\text{--}700\text{ cm}^{-1}$ (ν_4). Bands of lesser intensity appear at 1785 cm^{-1} and $1060\text{--}1080\text{ cm}^{-1}$ (ν_1). Another absorption area in the range of $2520\text{--}2650\text{ cm}^{-1}$ exists in both the nacreous and prismatic powders.

In vitro Crystallization of Calcium Carbonate

Figure 3 shows the morphologies and FTIR spectra of the crystals grown on the coverslips with or without soluble matrix from different origins. Figure 3a shows the morphology of crystals with-

Figure 2. Fourier transform IR spectrometer (FTIR) spectrum (reflectance) of powdered prismatic (a) and nacre (b) (mineral and organic matrix) from *Haliotis discus hannai* Ito.

out matrix protein supplementation. Rhombohedral calcite crystals were observed in the absence of matrix protein.

Figure 3b shows the morphology of crystals grown in the solution with prismatic soluble proteins and its FTIR spectra. The family of proteins from the prismatic layer induced a habit modification in calcite growth, yielding globular growth instead of the rhombohedra obtained in the absence of proteins. This may be the result of their relatively different rates of growth in the various directions. In the control treatment (Fig. 3a), calcite crystals show fuzzy step edges and the corners between step edges are sharp, whereas in the calcite grown in the presence of prismatic soluble matrix, step edges appear highlighted and corners between edges have become round.

In the nacreous soluble matrix supplemented solution, only aragonites are deposited, identified by the splitting of ν_4 in the FTIR spectra of deposited crystals as shown in Figure 3c. Hedgehog-like aggregates, with outward-oriented needles and their agglomerates, are formed.

DISCUSSION

In the present study, FTIR spectra showed an absorption area in the range of $2520\text{--}2650\text{ cm}^{-1}$ in both the nacreous and prismatic layer powder of *Haliotis discus hannai*, indicating the presence of HCO_3^- . FTIR analysis of the nacre from *Pinctada maxima* also found HCO_3^- group and demonstrated that HCO_3^- group participated in the formation of calcium carbonate (Balmain et al. 1999). Studies have shown that nacrein, a 60 kDa protein isolated from the EDTA-soluble organic matrix of both nacreous and prismatic layers of *Pinctada maxima*, exhibits carbonic anhydrase activity (CA), suggesting that carbonic anhydrase acts to catalyze HCO_3^- to carbonate ions at the site of crystal growth, and that this is important for the formation of both aragonite and calcite (Miyamoto et al. 1996, Miyashita et al. 2002).

In the in vitro crystallization experiment, the soluble matrix from the nacreous layer induced the formation of aragonite, whereas the soluble matrix from the prismatic layer induced the deposition of calcite. It can be presumed that the selection of crystal polymorph, by cooperative interaction with the soluble matrix, showed perfect arrangement with the polymorph of calcium carbonate from which the soluble matrix had been isolated, suggesting that the polymorph selection of crystal is mediated by the differential production of these two different families of soluble matrix. The present results, and previous findings in other mollusk species (Belcher et al. 1996, Falini et al. 1996), have demonstrated that soluble matrix proteins, rather than insoluble ones, can control crystal polymorphism in vitro.

The deposition of less stable aragonite crystals was induced by the soluble matrix from the nacreous layer. Meanwhile, the screw character of calcite was deposited in the prismatic soluble matrix supplemented solution. These results indicate a strong interaction between the acidic groups present in the proteins and the growing crystals. It has been proposed that the interaction of proteins with specific crystal planes is governed by intrinsic stereochemical recognition of the macromolecules for specific molecular motifs exposed on certain crystal planes, which implies the stimulation of crystal formation at certain sites and relatively inhibition of the process at all other sites (Weiner & Addadi 1991, Mann et al. 1993). It is suggested that the nature and organization of functional groups at the surface of the proteins are crucial to achieve the desired selectivity in polymorph nucleation, as well as controlling the crystalline nature and morphology of the inorganic phase.

Figure 3. Optical micrographs show some of the salient features of crystals in control (a) and formed in the presence of 10 µg/mL soluble matrix from prismatic layer (b) and nacreous layer (c) in the shell of *Haliotis discus hannai* Ino, respectively.

The weakness of the present study is that unpurified proteins have been applied in the *in vitro* mineralization experiments. It remains to determine which, if any, of the polyanionic proteins become occluded within the growing crystals, and with which crystallographic faces the individual proteins interact. To understand the underlying mechanisms of the interactions between proteins and mineral, it is essential to know the primary structure of the proteins involved. As a systematic work, we have purified the most dominate soluble protein in the nacre layer to

homogeneity and a molecular approach is underway (unpublished data).

MORPHOLOGICAL CHANGES IN THE RADULA OF ABALONE *HALIOTIS DIVERSICOLOR AQUATILIS* FROM POST-LARVA TO ADULT

TOSHIHIRO ONITSUKA,^{1*} TOMOHIKO KAWAMURA,¹ SATOSHI OHASHI,²

ABSTRACT The radula morphology of *Haliotis diversicolor aquatilis* was examined by SEM from postlarval to adult stages. In postlarvae of ~0.5 mm SL, a rachidian tooth (R), 2 pairs of lateral teeth (L1, L2), and 2–3 pairs of marginal teeth (M) per row were present. Only the number of marginal teeth increased to 12–13 pairs per row by 1.5 mm SL. An additional 2 pairs of lateral teeth (L3, L4) were added progressively from 1.5–2 mm SL. The L5 teeth were added at about 6 mm SL. Postlarvae with <2 mm SL had strongly curved rachidian and lateral teeth with clearance angles of ~15° to 20°. Each tooth had many serrations on the working edges. These structures of the teeth are probably suitable for collecting biofilm components such as extracellular mucus of diatoms. Postlarvae with >2.5 mm SL had higher clearance angles of 20° to 35°. Serrations on the working edges of rachidian and lateral teeth became progressively shallower. These changes suggest that the teeth are more suitable for grazing substrata to efficiently remove strongly attached diatoms. As abalone grew larger than 2 mm SL, the L3 and L4 teeth became longer than R, L1, and L2. The radula development of *H. diversicolor aquatilis* shown in this study is similar to that of *H. discus hannai*. However, it is suggested that the feeding transitions in the postlarval stage occur later in *H. diversicolor aquatilis* than in *H. discus hannai*. The morphology of juvenile and adult radula teeth of *H. diversicolor aquatilis* is clearly distinguishable from that of *H. discus hannai*. The sizes of L4 and L5 teeth of juvenile and adult *H. diversicolor aquatilis* were much smaller than L3 teeth, whereas sizes of L3–L5 teeth were not clearly different in *H. discus hannai*. This difference in radula morphology in juvenile and adult stages suggests that the main food items for juvenile and adult *H. diversicolor aquatilis* may be different from those of *H. discus hannai*.

KEY WORDS: abalone, radula, development, morphological changes, feeding, *Haliotis diversicolor*

INTRODUCTION

Haliotis diversicolor aquatilis Reeve 1846 is a commercially important abalone in Japan. However, the catch of this species has been declining probably because of over-fishing. Because reseeded hatchery-reared juveniles into wild populations has been conducted in many places to enhance the stocks, ecologic studies of this species have been very limited, especially in the early life stages. Since 2001, we have started studying the reproduction and early life ecology of *H. diversicolor aquatilis* at Nagai in Sagami Bay, Japan. Natural recruitment of this species at Nagai seemed relatively high in comparison with those of other abalone species (*H. discus discus* Reeve 1846, *H. madaka* Habe 1979 and *H. gigantea* Gmelin 1791) in the same area, but growth and survival rates of postlarval *H. diversicolor aquatilis* was variable among sampling areas (Onitsuka et al. unpublished).

Quantity and quality of food are important factors affecting the growth and survival of postlarval abalone (Kawamura et al. 1998), and these factors have been suggested to be critical in controlling recruitment of *H. discus hannai* Ino 1953 (Kawamura et al. 2002). Feeding habits in the early life stages of abalone have been studied in detail for *H. discus hannai* in recent years (reviewed by Kawamura et al. 2002, Takami & Kawamura 2003), and three major transitions in feeding have been identified (Kawamura et al. 1998, Takami & Kawamura 2003). The transitions in feeding are suggested to be closely related to structural and functional changes in the radula during postlarval and juvenile stages (Kawamura et al. 2001). However, there is little information concerning the feeding habits of *H. diversicolor aquatilis*, and the diets in the early life stages are generally unknown, as well as for other many abalone

species. In addition, the radula morphology of *H. diversicolor aquatilis* has only been examined for adults (Wu 1991). In the present study, changes in radula morphology of *H. diversicolor aquatilis* are described from postlarva to adult. By comparing the radula development with that of *H. discus hannai* (Kawamura et al. 2001) we try to estimate the feeding habits of *H. diversicolor aquatilis* in postlarval and juvenile stages.

MATERIALS AND METHODS

Abalone Rearing

Larval *H. diversicolor aquatilis* were hatched in October 2000, September 2001, and August 2002 at the Nagasaki Prefectural Institute of Fisheries (Nagasaki, Japan). One-day-old larvae were transferred to culture tanks with plastic plates covered with naturally appeared benthic diatoms as settlement plates. Postlarvae that settled on the plates were reared continuously in sand-filtered running seawater at 20°C.

In this study, we defined the boundary between postlarval and juvenile *H. diversicolor aquatilis* as the size at which the first respiratory pore is sealed (~2.5 mm SL, Onitsuka et al. unpublished), following the definition for *H. discus hannai* by Takami (2002). We call individuals larger than 35 mm SL adults according to Oba (1964).

Radula Observation

Samples of postlarvae and juveniles were preserved in 5% formalin in seawater at intervals of 3 days from 10 to 25 days postfertilization, and at 55 days and 163 days postfertilization in 2002. One, 3, 4, and 16-mo-old juveniles in 2001, 28-mo-old juveniles in 2000 were also preserved in 5% formalin in seawater. Radulae of postlarvae and small juveniles were removed with a pipette under

*Corresponding author. E-mail: oni2z@ori.u-tokyo.ac.jp

an inverted microscope following dissolution of tissues by soaking in sodium hypochlorite (0.6% Cl concentration; Wako Pure Chemical Industries Ltd. Osaka, Japan) for several minutes. Radulae were then serially pipetted through several distilled water baths to remove residual sodium hypochlorite. This procedure has been shown to preserve the structure of radula teeth (Kawamura et al. 2001). Abalone size represented by the longest shell length (SL) was measured individually before dissolution. Radulae of large juveniles and adults were dissected from preserved animals under a dissecting microscope after measuring shell length. The radulae were soaked in sodium hypochlorite to dissolve surrounding tissues attached to the radulae and then washed with distilled water to remove residual sodium hypochlorite. Because we could not get adult abalone from the hatchery, wild adult *H. diversicolor aquatilis* of 52.5–76.9 mm SL were caught at Nagai in 2002 as adult samples.

Radula length, width, number of transverse rows of teeth (Fig. 1A), and number of lateral and marginal teeth per row (except for individuals smaller than 6.5 mm SL) were determined using a monitor and digital camera system with an image analyzer, connected to an inverted microscope and a dissecting microscope. Radulae were then transferred to scanning electron microscope (SEM) stubs, laid flat with the teeth upward, and allowed to air dry before sputter coating with platinum for SEM observations.

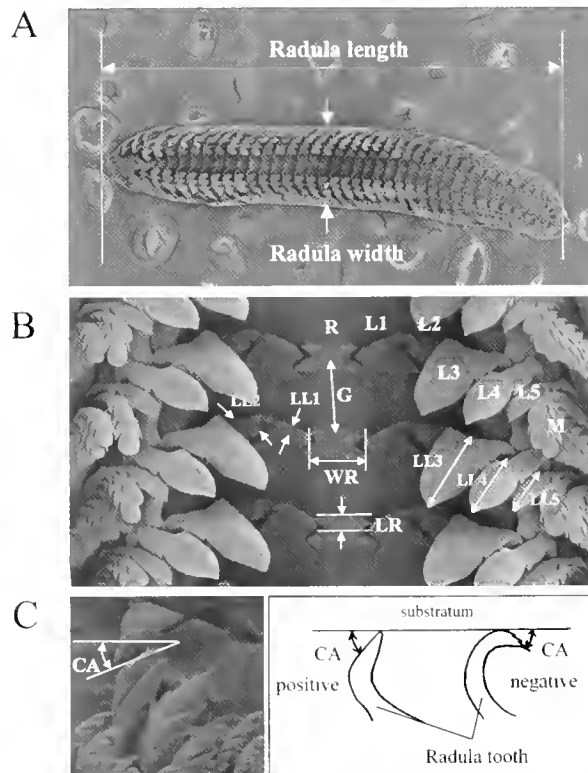

Figure 1. Scanning electron micrographs and an illustration describing radula morphology. (A) An entire radula showing length and width measurement. (B) Transverse rows of radula teeth. Tooth types: R = rachidian, L1–L5 = lateral teeth 1–5, M = marginal teeth. Measurements: WR = width of rachidian tooth, LR = length of rachidian tooth, LL1–LL5 = length of L1–L5 teeth, G = gap between rachidian teeth of adjacent transverse rows. (C) Side view of a row of radula teeth showing individual teeth. CA = clearance angle (positive). (D) A single tooth in profile illustrating positive (left) and negative clearance angle (right).

The length and width of rachidian teeth, lengths of the lateral teeth, gap between the rachidian teeth of adjacent transverse rows (Fig. 1B), and number of lateral and marginal teeth per row were measured using SEM photographs. Relative length of L4 and L5 teeth to L3 teeth was also calculated. The clearance angle of rachidian and lateral teeth (L1, L2; Fig. 1C, D) of postlarval and juvenile (<10 mm) radula, which was suggested to provide information on the function of radula teeth (Padilla 1985), was measured using the method by Roberts et al. (1999b). These measurements were done for five teeth (R, L1, L2) on a row located in the middle part of the whole radula. The clearance angles of older juvenile and adult radula were not measured because accurate measurements were obstructed by the overhanging marginal teeth. Measurements of the angles of rachidian teeth and inner lateral teeth of juveniles and adults could not be performed because they were located behind the lengthened outer laterals.

RESULTS

During the postlarval and juvenile period the radula underwent various morphologic developments before reaching the adult form. Most developments correlated more strongly with shell length than age (Table 1), so the following description relates primarily to shell length.

Overall radula length increased linearly with shell length (Fig. 2). However, the factors determining length changed as the abalone developed. During the early post larval period (<0.8 mm SL), the number of transverse rows of teeth was the main factor for increasing radula length. The radula of postlarvae with ~0.5 mm SL contained 19 to 21 rows of teeth, and the number of rows increased to 22 to 26 at ~0.8 mm SL (Fig. 3B). Late postlarvae (0.8–2 mm) had 22 to 26 rows of teeth, therefore the increase in radula length reflected an increased gap between adjacent rows of teeth (Fig. 2) and an increased length of rachidian and lateral teeth (indicated by rachidian and L3 in Fig. 2). The number of rows of teeth started increasing again above a size of 2 mm (Figs. 3A, B). Above 1.5 mm SL the gap between rows of teeth increased rapidly (Fig. 2) as differentiation of the L3–L5 teeth developed. Therefore, the increase in radula length of abalone >2 mm SL was caused by increases in row number (Figs. 3A, B), the gap between rows of teeth and teeth length (Fig. 2).

The width of the radula also increased linearly as abalone grew (Fig. 4). The increase in radula width for postlarvae was mainly caused by the increase in the number of marginal (Fig. 5) and lateral teeth per row (Fig. 6). Postlarvae with ~0.5 mm SL contained the rachidian tooth (R), 2 pairs of lateral teeth (L1 and L2),

TABLE 1.

Correlation of radula variables with post-larval age and post-larval shell length. Post-larvae were chosen to include a range of sizes for each age. Data are Pearson's correlation.

Variable	Shell Length	Age	n
Overall length of radula	0.998	0.953	76
Overall width of radula	0.992	0.964	76
Number of rows of teeth on radula	0.979	0.943	76
Width of rachidian tooth	0.971	0.901	31
Length of rachidian tooth	0.937	0.899	31
Gap between adjacent rachidian teeth	0.977	0.944	31
Number of lateral teeth per row	0.934	0.886	31

Figure 2. Increase in radula length with abalone shell length, from postlarva to adult. Graphs plot factors contributing to the change in radula length: the length of rachidian tooth, length of L3, and gap between rachidian teeth in adjacent transverse rows.

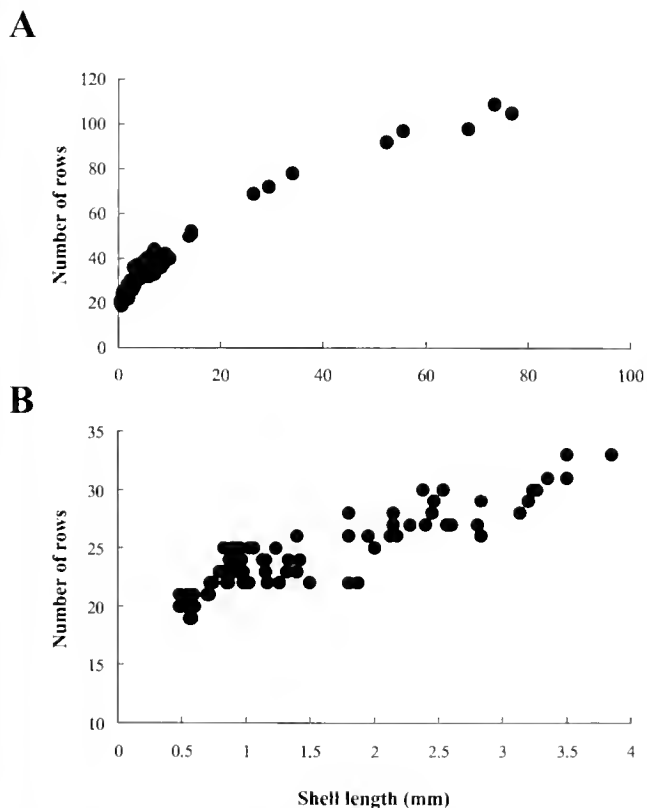

Figure 3. Relationship between abalone shell length (SL) and number of transverse rows. (A) Increase in number of transverse rows from postlarva to adult. (B) Number of transverse rows of postlarvae <4 mm SL.

and 2 to 3 pairs of marginal teeth per row (Fig. 7A), although lateral and marginal teeth were not clearly differentiated. The number of marginal teeth per row increased progressively; postlarvae with shell lengths of 1.5, 6, and ≥ 30 mm had 12–13, 30–40, and 70–80 pairs of teeth respectively (Fig. 5). Postlarvae smaller than 1.5 mm SL contained only 2 pairs of lateral teeth (L1 and L2) (Fig. 7B). Two additional pairs of lateral teeth (L3 and L4) were added progressively in animals with ~ 1.5 mm to ~ 2 mm SL (Fig. 6). A pair of L5 was added in animals with about 6 mm SL, and at this size the adult complement of lateral teeth was completed (Fig. 6). The increase in width during juvenile stage was caused mainly by the increase in width of the individual teeth (illustrated by the width of the rachidian teeth in Fig. 4) and by the increase in the number of marginal teeth per row (Fig. 5). The increase in radula width of adults was caused by the increase in width of the individual teeth (Fig. 4).

Changes in the Morphology of Individual Teeth

The serrations on the working edges of the rachidian and lateral teeth became less pronounced as abalone grew. R, L1, and L2 teeth

Figure 5. Relationship between abalone shell length (<70 mm SL) and number of pairs of marginal teeth in each transverse row. Each data point shows the mean \pm SE of 5 rows from 1 radula.

Figure 6. Relationship between abalone shell length (<10 mm SL) and number of pairs of lateral teeth in each transverse row.

initially had long, pointed serrations (Figs. 7A, B). In animals with more than 1 mm SL, these serrations became progressively shallower, first on R, and later on L1 and L2 as L3–L5 developed. By approximately 2 mm SL, nearly all serrations had disappeared from R, L1, and L2 teeth, but L3 and L4 retained serrations on their edges (Figs. 7D, E). All serrations disappeared from L3–L5 teeth in adult radula (Fig. 7F).

The L3–L5 teeth were already slightly longer than R, L1, and

Figure 7. Scanning electron micrographs of the radula showing developmental stages. (A) Postlarva with 0.48 mm SL, 2 + 2 + R + 2 + 2. (B) Postlarva with 1.4 mm SL, 8 + 2 + R + 2 + 8. (C) Postlarva with 1.8 mm SL, 13 + 3 + R + 3 + 13. (D) Juvenile with 4.4 mm SL, 34 + 4 + R + 4 + 34. (E) Juvenile with 9.2 mm SL, ~50 + 5 + R + 5 + ~50. (F) Adult with 76.9 mm SL, ~90 + 5 + R + 5 + ~90. R = rachidian, L1–L5 = lateral teeth 1–5, M = marginal teeth. Radula formulae represent numbers of M + L + R + L + M (Voltzow 1994).

L2 when they were added, but difference became greater as abalone grew (Figs. 7D–F, Fig. 8A). This differentiation of the lateral teeth accompanied an increase in the gap between adjacent rows of teeth (Fig. 2). The L3–L5 teeth became pointed, similar to canine teeth, whereas the tip of R and L1 teeth became flat, similar to spades (Fig. 7F), during the juvenile and adult stages. The L2 teeth of adults were longer and much more pointed at the tip than R and L1, but much shorter than L3. The sizes of outer lateral teeth (L3–L5) were different in juvenile and adult radula. The relative lengths of L4 and L5 teeth to L3 teeth were 0.7 and 0.5 (Fig. 8B), although their shapes were similar (Figs. 7E, F). The size of L5 teeth was almost the same as marginal teeth, but much more pointed at the tip than marginals (Fig. 7F).

Marginal teeth were narrow and comb-like, with many fine serrations present from postlarva to adult (Fig. 7). The size of individual marginal teeth relative to the rachidian and lateral teeth became smaller, and the tip of marginal teeth became more round as abalone grew. The marginal teeth of adult abalone retained serrations on their edges, but the serrations became less pronounced near the tip (Fig. 7F).

Post-larval abalone smaller than about 2 mm SL had strongly curved rachidian and lateral teeth (Fig. 9A) with mean clearance angles of about -15° to 20° (Fig. 10), although the angle was variable within and between radulae. The clearance angle increased in the late postlarval stage between 2–2.5 mm SL, and the rachidian and lateral teeth of juveniles (>2.5 mm SL) had higher clearance angles of 20° to 35° (Figs. 9B, 10).

DISCUSSION

Morphology of Adult Radula

Kawamura et al. (2001) showed that the development of the radula of *H. discus hannai* was remarkably similar to that of *H. iris*

Figure 10. Relationship between teeth clearance angle and shell length of postlarva and juvenile *Haliotis diversicolor aquatilis*. Each data point shows the mean \pm SE of 5 teeth from 1 radula.

Gmelin 1791 (Roberts et al. 1999b). The morphology of adult teeth was not clearly distinguishable between the two species. These two species are not genetically close (Lee & Vacquier 1995), but their feeding habits and growth patterns are similar (Kawamura et al. 1998). The radula teeth of adult *H. diversicolor aquatilis*, shown in this study, were easily distinguished from the radula of *H. iris* (Roberts et al. 1999b) and *H. discus hannai* (Kawamura et al. 2001). The size of outer lateral teeth (L3–L5) was apparently different in *H. diversicolor aquatilis*, L3 was the largest and L5 was the smallest (Figs. 7D–F, 8), while sizes of L3–L5 teeth were not clearly different in *H. iris* and *H. discus hannai*. Similar differences in the size of L3–L5 teeth were seen in tropical small abalone species *H. asinina* Linnaeus 1758, *H. ovina* Gmelin 1791 (Chitramvong et al. 1998), and *H. varia* Linnaeus 1758 (Wu 1991); but greater differences were observed in *H. diversicolor aquatilis*. The different morphologies of adult radula teeth may indicate different feeding habits among abalone species.

Development Process of Radula

The development process of the radula in *H. diversicolor aquatilis* was similar, but generally slower than in *H. iris* (Roberts et al. 1999b) and *H. discus hannai* (Kawamura et al. 2001). The initial increase in the number of teeth rows after metamorphosis was observed until the animal reached ~ 0.8 mm SL in *H. diversicolor aquatilis* (Fig. 3B), whereas in *H. iris* (Roberts et al. 1999b) and *H. discus hannai* (Kawamura et al. 2001) it was until ~ 0.5 mm SL. However, the size at which the row number started increasing again was ~ 2 mm SL in *H. diversicolor aquatilis*, which is smaller than the size of the animal with 4–5 mm SL reported for *H. discus hannai* (Kawamura et al. 2001). The mean postlarval size (the longest dimension of the larval shell) at metamorphosis of *H. diversicolor aquatilis* (257 μ m) is smaller than that of *H. discus hannai* (277 μ m) (Hayashi 1983). The remarkable increase in clearance angle of rachidian and lateral teeth was observed at 2–2.5 mm SL in *H. diversicolor aquatilis* (Fig. 10), whereas it is noticed at ~ 1 mm SL in *H. iris* (Roberts et al. 1999b) and *H. discus hannai* (Kawamura et al. 2001). The L5 teeth were added completing the adult complement of five pairs of laterals at ~ 6 mm SL in *H. diversicolor aquatilis* (Fig. 6), whereas at ~ 1.7 mm SL in *H. iris* (Roberts et al. 1999b) and at ~ 2 mm SL in *H. discus hannai* (Kawamura et al. 2001).

Estimated Transitions in Feeding

Three major transitions in feeding have been identified in *H. discus hannai* (Kawamura et al. 1998, Takami & Kawamura 2003), which appears to be closely related to radula development (Kawamura et al. 2001). The first transition is from lecithotrophy to particle feeding, around the time of metamorphosis. Postlarval *H. iris* (Roberts et al. 1999a) and *H. discus hannai* (Seki & Kan-no 1981, Kawamura & Takami 1995) begin feeding, within a day of the velum being shed, on the surface of crustose coralline algae (CCA) where larval abalone preferentially settle in the natural environment (e.g., Saito 1981, Morse & Morse 1984). However, postlarvae can grow up to ~ 0.4 mm SL without food during several days following metamorphosis (Roberts et al. 2001, Takami et al. 2000) by using their residual yolk supply as an energy source (Roberts et al. 2001, Takami et al. 2002). The early increase in the number of teeth rows was suggested to be related to the first transition in feeding, indicating active formation of new rows of

teeth prior to shedding anterior worn teeth during feeding (Kawamura et al. 2001). The greater size at which *H. diversicolor aquatilis* concluded the initial addition of teeth rows (0.8 mm SL) may indicate longer contribution of residual yolk reserves as an energy source after metamorphosis for this species. After the initial increase, the number of rows remained relatively constant until ~2 mm SL and then started increasing again (Fig. 3B). In *H. discus hannai* the number of rows was relatively constant between ~0.5 mm and 5 mm SL (Kawamura et al. 2001), which is longer than in *H. diversicolor aquatilis* in the present study. The factors controlling the increasing number of rows are not known, but this may be an interesting difference between the two abalone species.

Clearance angles of zero or less were suggested to indicate teeth would slide across the surface rather than cutting it (Padilla 1985). The curved radula teeth of postlarval *H. diversicolor aquatilis* <2 mm SL are probably suitable for collecting biofilm materials such as extracellular mucus secretions of diatoms, as suggested for postlarvae <1 mm of *H. iris* (Roberts et al. 1999b) and *H. discus hannai* (Kawamura et al. 2001). The increase in clearance angle in *H. discus hannai* of approximately 1 mm SL appeared to be related to the second transition in feeding, main diets being from mucous materials to tightly attached diatoms such as *Cocconeis* spp. colonizing on CCA (Kawamura et al. 2001). Postlarval *H. discus hannai* >1 mm SL with positive clearance angles of radula teeth seem able to detach *Cocconeis* cells from CCA surfaces, whereas smaller postlarvae with curved radula teeth cannot efficiently detach diatom cells (Kawamura et al. 2001). *H. diversicolor aquatilis* appears to efficiently detach strongly attached diatoms from CCA surfaces at 2–2.5 mm SL when the radula teeth have higher clearance angles. Biofilm components such as extracellular secretions from diatoms and/or from CCA can be important food sources for postlarval *H. diversicolor aquatilis* <2 mm SL, which is larger than in *H. discus hannai* (<1 mm SL). However, the size of food items that can be collected by the radula seems to increase with a reduction in tooth serrations (1 mm SL, Fig. 7) and an increase in the gap between the adjacent rows of teeth of postlarvae (>1.5 mm SL, Fig. 2). It should be noted here that the clearance angle at the point of contact with food items can change depending on various factors, such as the position of the radula when it protrudes for feeding, flexing of the radula during feeding, and the nature of the substrate. Our clearance angle data are based on the radulae removed from abalone and prepared for SEM. Therefore, the above discussion on the implications of feeding due to increased clearance angles is conjectural, as discussed previously in Roberts et al. (1999b) and Kawamura et al. (2001).

The L3–L5 teeth of juveniles and adults were sharply cusped without serrations and stood much higher above the radula membrane than rachidian and L1 and L2 teeth (Figs. 7D–F), suggesting that they are suitable for cutting firmly attached algae and/or for excavating substrata, as discussed for *H. iris* (Roberts et al. 1999b) and *H. discus hannai* (Kawamura et al. 2001). The differentiation of the L3–L5 teeth was considered to be related to the final transition in feeding of *H. discus hannai*, from microalgal to macroalgal feeding (Kawamura et al. 2001), though the marked increase in the activity of the macroalgal polysaccharide degrading enzymes observed at about 2 mm SL also appeared to contribute to the efficient utilization of macroalgae (Takami et al. 1998). In fact, postlarval *H. discus hannai* >1.8 mm SL used juvenile macroalgae *L. japonica* Areschoug 1851 efficiently (Takami 2002) after the

differentiation of lateral teeth, that started at ~1.5 mm SL (Kawamura et al. 2001). Although the adult complement of five pairs of laterals was completed at ~6 mm SL in *H. diversicolor aquatilis* (Fig. 6), the differentiation of the L3 teeth started at ~1.5 mm SL (Fig. 2) from the time they appeared. This suggests that *H. diversicolor aquatilis* also starts utilizing juvenile macroalgae in the late postlarval stage. Hence, *H. diversicolor aquatilis* may not need to use tightly attached diatoms before they start feeding on juvenile macroalgae, because they can feed and grow on biofilm mucus materials until ~2 mm SL, as discussed earlier.

Juveniles of *Haliotis discus hannai* and its subspecies *H. discus discus* initially feed on juvenile macroalgae (Maesako et al. 1984, Takami 2002) and/or soft algae such as *Ulva* spp. (Seki 1997). They began feeding on adult macroalgal fronds such as *Laminaria* and *Eisenia* once they became larger than ~13 mm SL (Seki 1997). The morphology of juvenile and adult radula teeth of *H. diversicolor aquatilis* is different from that of *H. discus hannai*. The sizes of L4 and L5 teeth of juvenile and adult *H. diversicolor aquatilis* were much smaller than L3 teeth (Figs. 7D–F, Fig. 8). Although we do not know how the abalone use different types of the radula teeth during feeding, the difference in radula morphology suggests that the main food items for juvenile and adult *H. diversicolor aquatilis* are different from *H. discus hannai*.

By comparing the radula morphology and its development with those of *H. discus hannai*, we can estimate the transitions in feeding of *H. diversicolor aquatilis* as earlier mentioned. Three possible differences in feeding and nutritional sources between the two species, which may be important from the ecologic point of view, can be considered: (1) The longer contribution of the residual yolk reserve as an energy source after metamorphosis is suggested for *H. diversicolor aquatilis*. This may mean longer starvation tolerance of newly metamorphosed postlarvae with limited and/or unsuitable food sources, or longer swimming larval life if they fail to contact an appropriate environmental stimulus for metamorphosis than those of *H. discus hannai* (Takami et al. 2000, Takami et al. 2002). (2) Because the differentiation of outer lateral teeth started almost at the same time of increasing clearance angles, main food items for *H. diversicolor aquatilis* can possibly transfer directly from biofilm mucus materials to juvenile macroalgae, and tightly attached diatoms may not be an essential food source in between them. Competition for tightly attached diatoms on CCA habitats between other herbivore gastropods was suggested to be a critical factor affecting the survival and growth rate of *H. discus hannai* (Takami et al. 2001, Kawamura et al. 2003). If the diatoms would not be necessary, the feeding and growth of *H. diversicolor aquatilis* could be more flexible than *H. discus hannai*. (3) The difference in the main food items for juveniles and adults between the two species, suggested in this study, may reflect differences in their actual habitats. The adults *H. diversicolor aquatilis* inhabit shallow boulder areas where large macroalgal forests are limited, whereas adult *H. discus hannai* are in deeper rocky areas with macroalgal forests. Further field observations and laboratory experiments are needed to clarify the feeding and nutritional sources of *H. diversicolor aquatilis* throughout their life stages.

ABSTRACT The neurons containing serotonin and FMRF-amide were immunohistochemically localized in the cerebral, pleuropedal and visceral ganglia of *Haliotis asinina*. The large (~10 × 20 μm in diameter) and medium size (~7 × 10 μm in diameter) neurons of these three ganglia contained immunoreactivities to both antibodies against serotonin and FMRF-amide, whereas the more numerous small size neurons (<6 × 8 μm in diameter) did not show these immunoreactivities. The large neurons had oval-shaped nuclei containing mostly euchromatin and long cytoplasmic processes, whereas the medium size neurons, which could be neurosecretory cells, contained round nuclei with patches of heterochromatin and lack processes. The 5-HT immunoreactive cells were concentrated in the upper half of the medial edge of the cerebral ganglion, the edge of ventral and dorsal horns of the pleuropedal ganglion, and the right latero-ventral edge of the visceral ganglion; whereas the FMRF-amide immunoreactive neurons were concentrated in the dorsal and ventral edges of the cerebral ganglion, the edge of dorsal horn and the dorsal edge of the body of the pleuropedal ganglion, and the left latero-ventral and latero-dorsal edge of the visceral ganglion. The 5-HT cells were most numerous in the cerebral (~70/2,300 cells per section), and the pleuropedal ganglia (~120/2,700 cells per section), whereas they were least numerous in the visceral ganglion (~50/400 cells per section). The FMRF-amide cells were most numerous in the cerebral (~76/2,000 cells per section), and the pleuropedal ganglia (~130/2,500 cells per section), whereas they were least numerous in the visceral ganglion (~60/1,050 cells per section). The present study suggests that serotonin and FMRF-amide are major neurotransmitters in the neural ganglia, with only the large- and medium-sized neurons involved in the production and storage of these two neurotransmitters.

INTRODUCTION

Serotonin (5-hydroxytryptamine; 5-HT) and tetrapeptide Phe-Met-Arg-Phe-amide (FMRF-amide) are neurotransmitters that play many important roles in controlling the physiologic and behavioral processes of invertebrates (Kuang et al. 2002, Mercier et al. 2003). In molluscs, 5-HT controls heartbeat (Skelton et al. 1992), locomotion (McClellan et al. 1994, Satterlie & Norekian 1995), feeding (Kupfermann & Weiss 1981), memory and learning (Nelson & Alkon 1997), and reproduction (Ram et al. 1996, Juneja & Koide 1996). FMRF-amide can evoke muscle tension (Schot & Boer 1982, Buckett et al. 1990), modulate cardiac output (Buckett et al. 1990), and reproduction (Lehman & Greenberg 1987). By immunolocalization methods, 5-HT and FMRF-amide have been observed in many ganglia of the central nervous system (CNS) of gastropod molluscs (Audesirk 1985, Elekes 1992, Croll et al. 2001, Fickbohm et al. 2001), especially in the pulmonate snails, *Helix pomatia* and *Helix aspersa* (Griffond et al. 1986, Lehman & Price 1987, Hernadi et al. 1989, Elekes & Nassel 1990, Hernadi 1992). Other gastropods that have also been investigated are a sea hare *Aplysia kurodai*, a land snail *Achatina fulica* (Fujii & Takeda 1988), an aquatic snail *Lymnaea stagnalis* (Audesirk 1985), and an opisthobranch *Phestilla sibogae* (Croll et al. 2001). The 5-HT and FMRF-amide immunoreactive neurons have been identified in the CNS of all these species with specific distribution patterns. For example, in *Aplysia kurodai* and *Achatina fulica*, the 5HT-immunoreactive cells and neuropils were observed in all ganglia

except the left pleural ganglia. The sizes of these neurons are generally large, and some reach up to 50–70 μm in diameter. FMRF-amide immunoreactive neurons have been located throughout the central ganglia (cerebro-pleural, parietal, pedal, and visceral ganglia) of *Phestilla sibogae*, and about 65–100 intensely labeled neurons were observed in these ganglia, whereas another 40–45 neurons were weakly or variably stained (Croll et al. 2001). A similar study has been done in an aquatic snail, *Lymnaea stagnalis*, in which FMRF-amide immunoreactive neurons and neuropils were consistently found in the cerebral, pedal, right parietal, and visceral ganglia (Audesirk 1985). Moreover, the colocalization of 5-HT and FMRF-amide has also been performed in a chiton, *Lepidopleurus asellus*, which is a primitive mollusc species (Moroz et al. 1994). Both types of neurons are distributed in characteristic patterns in the CNS (i.e., the 5-HT immunoreactive neurons are concentrated in the ventral cords while FMRF-amide immunoreactive neurons in the lateral cords). In addition, a tight network of 5-HT and FMRF-amide immunoreactive nerve fibers were found in the body wall and the foot muscle (Moroz et al. 1994). The prevalence of serotonergic and FMRF-amidergic neurons in the CNS in gastropods implies that they are important neurotransmitters in these animals.

In contrast to the higher gastropods, very few works along this line have been carried out in the primitive gastropods. Only two studies reported the presence of 5-HT in the cerebral ganglion of developing larvae of red abalone, *Haliotis rufescens* (Kataoka et al. 1987, Barlow & Truman 1992) and 5-HT-immunoreactive fibers in the outer zone of the retinal plexiform layer and the optic nerve trunk (Kataoka et al. 1987). In the present study, we have examined and compared the distribution of 5-HT and FMRF-

amidergic neurons in the neural ganglia of the CNS of *Haliotis asinina*, a tropical abalone commonly found in Thai coastal waters.

MATERIALS AND METHODS

Tissue Collection

Adult male *H. asinina* (age >16 mo) were collected from a land-based aqua culture system at Coastal Aquaculture Develop-

ment Center, Department of Fisheries, Prachaubkirkhun Province, Thailand. They were kept in concrete tanks housed in the shade and well flushed with mechanically circulated sand-filtered seawater and provided with an air delivery system to maintain the stable controlled environment. The optimum level of salinity is about 22.5–32.5 ppt and temperature –22 C to 26 C (Singhagravan & Doi 1999). They were fed with macroalgae (usually *Gracilaria* spp. and *Laminaria* spp.), supplemented with artificial food.

Figure 1. LM micrographs illustrating the location and characteristics of serotonergic neurons and nerve fibers in the cerebral ganglia of *H. asinina*: A. A negative control cross section showing a cerebral ganglion (CG) and nerve bundles (Nt) arising from the ganglion to buccal mass (Bu). D = dorsal, V = ventral, M = medial, Lt = left side, Rt = right side. B & C. 5-HT neurons (black dots- arrows), concentrated in the upper half of the cortex at the medial edge of the ganglion, with the immunoreactive nerve fibers (Nt) distributed throughout the neuropil of the ganglion, and the nerve branch running into the buccal mass (Bu). D. A high-power micrograph of the neuropil of a cerebral ganglion, showing the varicosities of 5-HT immunoreactive nerve fibers (Nt). E. A micrograph from the boxed area in C, showing a row of serotonergic neurons in the cortex of the ganglion. F & G. High-power micrographs of the two types of serotonergic neurons from E, the large neuron (NR) characterized by the presence of long axon (arrowheads), and the medium-size neurosecretory neuron (NS). No immunoreactivity is detected in the small neurons (arrows).

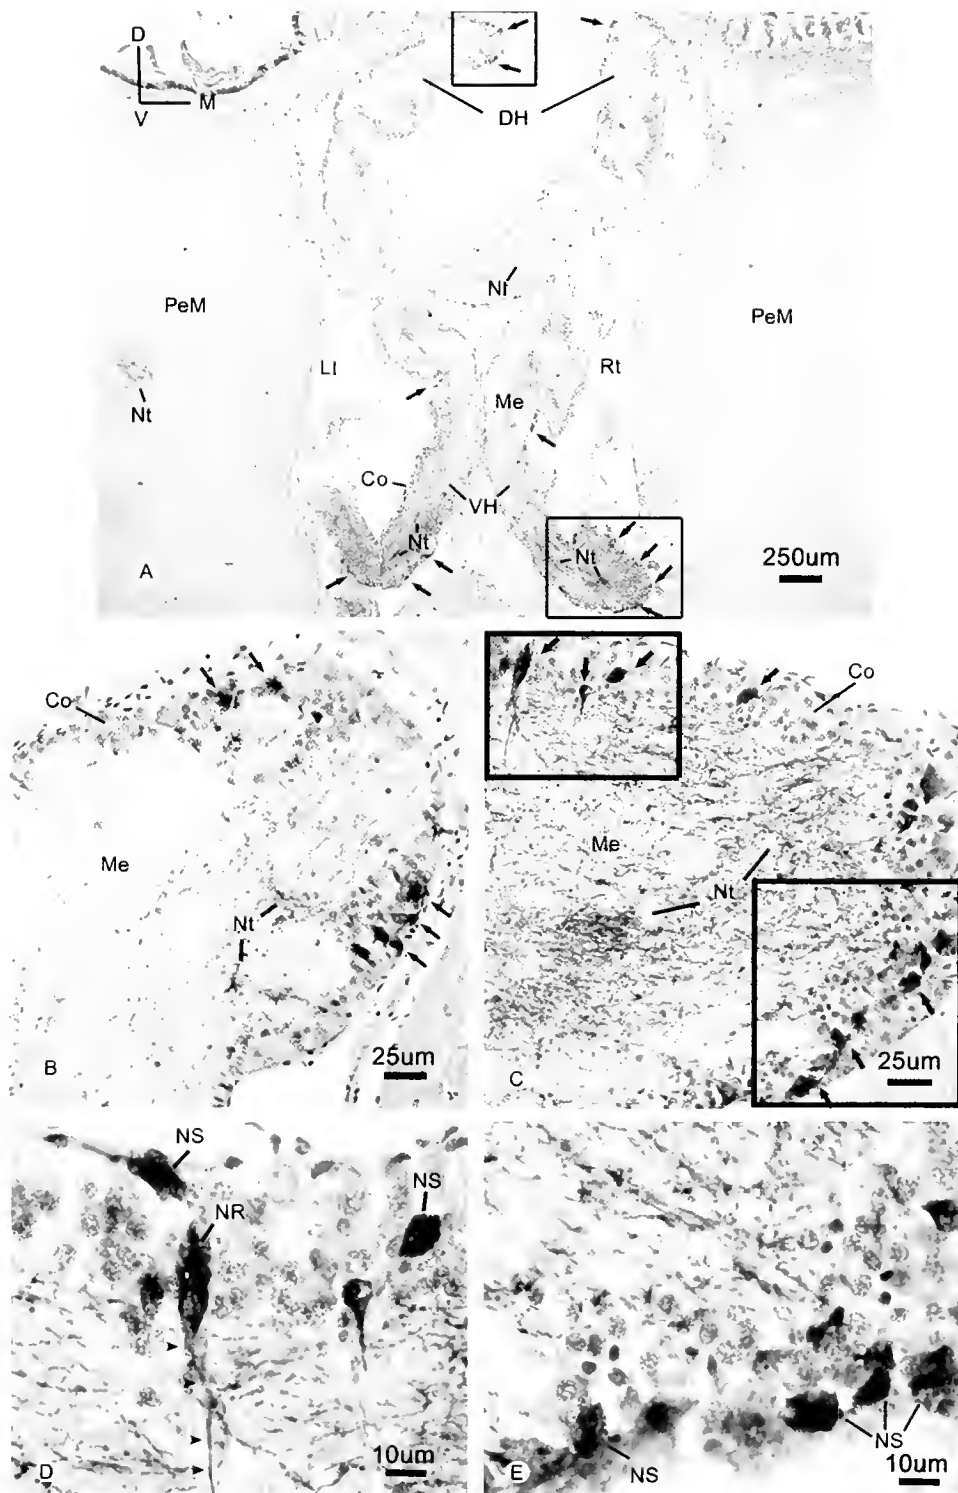

Figure 2. LM micrographs of a mid cross section of the pleuropedal ganglia of *H. asinina*, illustrating the distribution and characteristics of serotonergic neurons and nerve fibers. A. A low-power micrograph, showing the distribution of 5-HT neurons (arrows) concentrated in the upper or lower one-third of the cortex (Co) of the dorsal (DH) or ventral horns (VH). The positively stained nerve fibers (Nt) are also present in the medulla (Me) and pedal muscle (PeM). Lt = left, Rt = right, B & C. Medium-power micrographs of the boxed areas of left dorsal horn (B) and right ventral horn (C) in A, showing groups of serotonergic neurons (arrows) in the cortex (Co) and positively stained nerve fibers (Nt) in the medulla (Me). D & E. High-power micrographs of serotonergic neurons from the boxed area in C, showing the large size neuron (NR) characterized by the long axon (arrowheads), and medium-size neurosecretory cells (NS) without processes.

Antibodies Against 5-HT and FMRF-Amide

The rabbit polyclonal antibody against 5-HT was purchased from Zymed Laboratories Inc. For antibody against FMRF-amide, the peptide (Sigma Company) was dissolved in deionized water at

0.5 mg/mL. This solution was mixed with keyhole limpet hemocyanin (KLH) (10 mg/mL) in 1:1 ratio. Then, glutaraldehyde was added up to 0.375% with 1 M glycine-HCl. After that, the solution was mixed with 0.1 M phosphate buffered saline (PBS) containing complete Freund's adjuvant in 1:1 ratio for subcutane-

Figure 3. LM micrographs of a cross section of a visceral ganglion, illustrating the location and characteristics of serotonergic neurons and nerve fibers. A. A low-power micrograph, showing two groups of serotonergic neurons (arrows) in the right lateral (RL-arrows) and right latero-ventral (RLV-arrows) edge of the ganglion, whereas only few positive cells are found in the right and left dorsal edge (RD, LD-arrows). A few immunoreactive nerve fibers (Nt) are also present in the ganglion. B & C. Medium-power micrographs, showing groups of 5-HT neurons from the boxed areas in A, and the 5-HT immunoreactive nerve fibers in the medulla region. D & E. High-power micrographs, showing both types of large (NR) and medium (NS) size serotonergic neurons in the boxed areas in A.

ous injection into experimental mice (300 μ L/mouse). After 14 days, a similar dose of FMRF-KLH mixed with incomplete Freund's adjuvant was injected to boost the immune response of the animals. On day 49, the blood was collected from the heart bleeding and centrifuged at 5,000g, and the serum was collected, mixed with 20 folds in volume of KLH solution to preabsorb antiKLH in the antiserum. Then, the dot blot ELISA was used to detect the specificity of the mouse antiFMRF-amide polyclonal antibody, and make sure that antiKLH was completely absorbed. The pre-absorbed antiserum was used to stain the sections of cerebral, pleuropedal and visceral ganglia.

Immunoperoxidase Method

Ten adult male *H. asinina* weighing more than 20 g were anesthetized with 5% MgCl₂, then the shells were removed. Cerebral, pleuropedal, and visceral ganglia were dissected out and fixed in Bouin's solution at 4 C for 12–16 h. Specimens were washed in 70% ethanol for removal of the fixative. Then, they were dehydrated through a graded series of ethanol (70% to 100%) for 30–45 min each depending on the size of the specimens, cleared with dioxane, infiltrated and embedded in paraffin wax, and sectioned at 5- μ m thick. For immunostaining, the paraffin

sections of each ganglion were deparaffinized with xylene, rehydrated through a graded series of ethanol (100% to 80%), and finally in 70% ethanol containing 1% Lithium carbonate (LiCO₃). The endogenous peroxidase was blocked by treating the sections with 3% H₂O₂ in methanol for 30 min. Then, the sections were covered with 4% bovine serum albumin (BSA) in 100 mM phosphate buffered saline, containing 0.25% triton-X 100, pH 7.4 (PBST), for 30 min. Following the blocking step, the consecutive sections were incubated in either the rabbit anti5-HT or mouse antiFMRF-amide serum as the primary antibodies, for 1 h, at 37 C. After incubation, the sections were washed three times with PBST, then incubated in the HRP-conjugated goat antirabbit or anti mouse IgG as the secondary antibodies, for 30 min, at 37 C. Finally, the sections were immersed in the substrate solution containing 0.03% w/v DAB, 0.3% NiCl₃, and 0.1% H₂O₂ in 50 mM Tris buffer pH 7.2, washed several times with distilled water, counter-stained with Hematoxylin, and mounted in the permount solution. The sections were observed and photographed by a Nikon microscope equipped with digital camera DXM 1200. In addition, the numbers of serotonergic and FMRF-amidergic neurons in each ganglion of each abalone were counted and estimated as number of positive cells per total number of cells per section, which were taken at the middle of each ganglion.

Figure 4. A. Low-power micrograph of a cross section of cerebral ganglia showing the distribution of the FMRF-amide cells (black color) concentrated at the upper and lower parts of lateral and the dorso-medial edges of the ganglion. RESULTS

Immunohistochemical Localization

By using immunoperoxidase technique enhanced with nickel chloride (NiCl_2) we were able to localize two separate sets of neurons containing 5-HT and FMRF-amide in the cerebral, pleuropedal and visceral ganglia. The patterns of distribution of these two types of neurons in each ganglion are described below.

Cerebral Ganglion

The 5-HT cells are concentrated in the upper half of the cortex of medial edge of the ganglion (Figs. 1B, C, Fig. 7A), whereas there are few widely scattered 5-HT cells in the lateral edge of the ganglion. FMRF-amide cells are concentrated in the cortex of the dorsal and ventral edges of the ganglion whereas the lateral edge and the dorso-medial edge have only few widely scattered FMRF-amide cells (see Figs. 3A, B, Fig. 7A). Both 5-HT and FMRF-amide immunoreactive nerve fibers were also observed throughout the neuropils of the ganglia. The 5-HT immunoreactive nerves branching out from the ganglia were also observed around the head

Figure 5. A. Low-power micrograph showing the distribution of the FMRF-amide cells (black color) concentrated in the cortex of the upper one-third of both medial and lateral edges of the dorsal horn (DH), and the dorsal edge of the body part (Bo) of the pleuropedal ganglia. B & C. Medium-power micrographs of FMRF-amide immunoreactive cells in the cortex of left dorsal horn (LDH) and dorsal edge of the body (Bo) of pleuropedal ganglia. D. A high-power micrograph of left dorsal horn (DH) in A, showing immunoreactive large (NR) and medium size neurons (NS) in the cortex (Co), and nerve fibers with varicosities (arrows) in medulla (Me) of the ganglia.

and buccal areas of the abalone, but fewer FMRF-amide immunoreactive fibers were found (Fig. 1B, see Fig. 4A later). Based on the histologic characteristics, the serotonergic neurons could be classified into 2 types (i.e., the large and medium size neurons). The large oval or pyramidal shape neurons (about $10 \times 20 \mu\text{m}$) contain the oval-shaped nuclei with complete euchromatin, and usually large nerve processes (Figs. 1E, F), whereas the medium size neurons (about $7 \times 10 \mu\text{m}$), which could be neurosecretory cells, contain round nuclei with patches of heterochromatin (U'patham et al. 1998, Kruatrachue et al. 1999, Thongkukiatkul et al. 2000) and lacking processes (Fig. 1G). However, there was no immunoreactivity of 5-HT in the cell bodies of small neurons ($<6 \times 8 \mu\text{m}$) (Figs. 1F, G). Similarly, from the histologic characteristics, FMRF-amidergic neurons are also mostly the large size neurons and medium size neurons, with no staining in the small neurons (Figs. 4C, D). The number of 5-HT cells are about

70/2,300 cells per section in comparison to 76/2,000 cells per section for FMRF-amide cells.

Pleuropedal Ganglion

In pleuropedal ganglia, the 5-HT cells were found concentrated in the upper and lower one-third part of the dorsal and ventral horns of the ganglion (Fig. 2A to C, Fig. 7B) with widely scattered 5-HT cells on the lateral edge of the ventral horn (Fig. 2A, Fig. 7B). FMRF-amide cells were found concentrated in the cortex of the upper one-third of the dorsal horn and the dorsal edge cortex of the body, with few widely scattered positive cells in the ventral horn and the ventral edge of the body (Fig. 5A). The immunoreactivity of both types of nerve fibers were also found throughout the neuropils of the ganglia, especially in the dorsal and ventral horn regions, (Fig. 5A, C). Histologically, there are only two types

Figure 6. A. A medium-power micrograph and high-power micrographs (B, C, & D) of the visceral ganglion, showing the immunoreactive large (NR) and medium size neurons (NS) in the cortex (Co) of the left latero-ventral (LLV) and dorsal (LLD) edges of the ganglion.

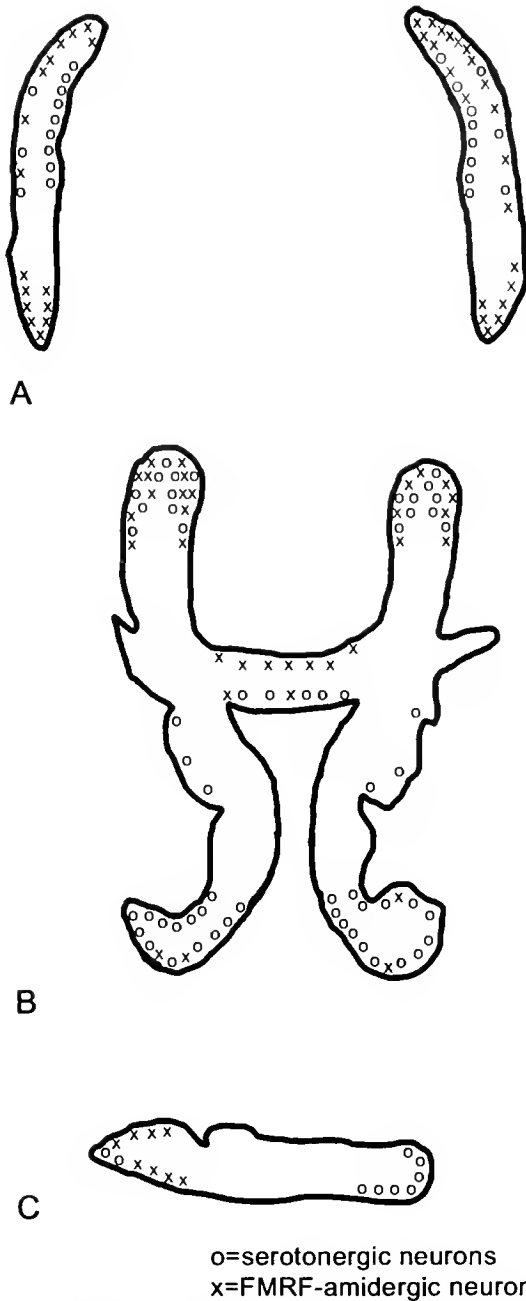

Figure 7. A schematic diagram summarizing the distinctive distribution patterns of 5-HT and FMRF-amide immunoreactive neurons in the cerebral A, pleuropedal B, and visceral ganglia C of adult *H. asinina*. O = serotonergic neurons, x = FMRF-amidergic neurons.

of immunoreactive 5-HT and FMRF-amide neurons with similar characteristic as those found in the cerebral ganglia (Figs. 2D, E, Fig. 5D). The numbers of both types of these neurons are approximately equal and they are evenly distributed in specific areas of the ganglia as mentioned. There are about 120/2,700 cells per section for serotonergic neurons in the ganglion, and about 130/2,500 cells per section for FMRF-amide cells.

Visceral Ganglion

The 5-HT neurons are concentrated on the right lateral and latero-ventral edge of the ganglion (Figs. 3A to C, Figure 7C),

while the FMRF-amidergic neurons are concentrated on the left latero-ventral and latero-dorsal edge (Fig. 6A, Fig. 7C). A few immunoreactive nerve fibers containing 5-HT and FMRF-amide were also observed in the neuropil of the ganglion (Figs. 3A to C). The two types of immunoreactive neurons for both 5-HT and FMRF-amide could also be identified, with similar characteristics as in the cerebral and pleuropedal ganglia (Figs. 3D, E, Fig. 6B to D). The number of serotonergic neurons is about 50/400 cells per section, whereas that of FMRF-amide cells is about 60/1,050 cells per section.

DISCUSSION

The distribution of 5-HT and FMRF-amide, the major neurotransmitters, have been widely studied in a number of invertebrates (Beltz & Kravitz 1983, Nassel et al. 1985, Fujii & Takeda 1988, Too & Croll 1995, Raikova et al. 2000) including the gastropod molluscs (Audesirk 1985, Elekes 1992, Croll et al. 2001, Fickbohm et al. 2001). However, most previous studies have been done in the opisthobranch and pulmonate species, the higher gastropods. Up to now, there are few works on the prosobranch including abalone, which belong to the most primitive subclass of gastropods (Barlow & Truman 1992).

In the present study, we have studied the distribution patterns of these two types of neurotransmitters in the central ganglia of *H. asinina*. The results showed the presence of immunoreactive 5-HT and FMRF-amide neurons in all three ganglia, with the distinctive distribution patterns in each ganglion as summarized in Figure 7. Both serotonergic and FMRF-amidergic neurons also showed a tendency to be grouped into clusters as in higher gastropods, whereas in species of the lower classes; such as, plathelminthes, annelida, and arthropoda, serotonergic neurons tend to be more widely scattered (Fujii & Takeda 1988).

H. asinina possesses a fairly high number of both serotonergic and FMRF-amidergic neurons in all three ganglia, especially in the pleuropedal ganglia. Fujii and Takeda (1988) found that the number of serotonergic neurons in invertebrates tends to increase in the higher phyla. Furthermore, it was found that one of the main factors that controls the number of 5-HT cells is the physiologic condition. In a snail *Helix pomatia*, it was reported that the number of serotonergic cells in the central ganglia changed with the physiologic conditions of the animals (i.e., they increased during active phase and decreased during hibernation) (Hiripi & Salanki 1973).

While the immunoreactive 5-HT and FMRF-amide neurons were observed in all three ganglia, the immunoreactive nerve fibers containing 5-HT were found concentrated in the neuropils of the ganglia, as well as in musculature of the head, buccal, and foot regions, whereas FMRF-amide fibers were only found in the neuropils and around the hemolymph sacs. These characteristics were similar to the higher gastropod molluscs (Schot & Boer 1982, Fickbohm et al. 2001). Therefore, it is possible that serotonergic neurons may play a primary role in controlling the muscle contraction for head and foot movement and feeding, as in other gastropods, whereas FMRF-amidergic neurons may function mainly as a neuromodulator in the CNS.

The sizes of both serotonergic and FMRF-amidergic neurons are different from those in other gastropods, especially in a pulmonate and opisthobranch molluscs, also in which the positive neurons showed remarkable size range (Fickbohm et al. 2001). In *H. asinina*, both immunoreactive neurons are confined to the large nerve cells with processes and the medium size nerve cells with no processes. The large neurons could be equivalent to the large neu-

rons as classified by Kruatrachue et al. (1999), which seem to be the motor neurons controlling the musculature of head, buccal, and foot region via their long axon. The medium size cells have all characteristics of neurosecretory cells (Kruatrachue et al. 1999). Interestingly all small size nerve cells, which are believed to be association or interneurons, are nonimmunoreactive. Thus, the strong presence of 5-HT and FMRF-amide in the CNS of *H. asinina* suggests that both neurotransmitters have important roles in

controlling the physiologic and behavioral responses of this animal as in the other gastropods.

ABSTRACT *Haliotis asinina*, a tropical abalone, has a pair each of cephalic, optic, appendage tentacles at the anterior end of the head, and numerous epipodial tentacles distributed on the periphery of its body. The cephalic and epipodial tentacles are essentially sensory organs with similar general structure. In a mature adult (about 16 mo-old), the cephalic tentacle measures about 3.77 cm in length and 0.14 cm in diameter, whereas the epipodial tentacle measures about 9.27 mm in length and 0.59 mm in diameter. In cross sections, each tentacle has a bundle of nerve fiber forming the core structure, surrounded by a thick layer of circular muscle, which also branches into radially oriented fibers. These fibers are interlaced with thick paraxially orientated fibers; together they account for the size and mobility of the tentacles. The surface of both types of tentacles can be divided into three parts: the basal part exhibits slight corrugation consisting of small folds alternated with grooves, the middle part has numerous short hillock-shaped papillae, and the top part has a very high concentration of cone-shaped papillae. Each papilla comprises a group of densely stained ciliated neuroepithelial cells, surrounded by lightly stained supporting epithelial cells bearing microvilli. Gamma amino butyric acid (GABA) was found, by immunohistochemistry, to be highly concentrated in the neuroepithelial cells. The rest of epithelium of both kinds of tentacles is of a columnar type, consisting of clear cells bearing microvilli and goblet cells. The GABA-containing neuroepithelial cells are scattered widely among them.

KEY WORDS: *H. asinina*, tentacle, histology, sensory receptor, GABA

INTRODUCTION

Tentacles are important sense organs of gastropods, which contain tactile and chemoreceptor cells in abundance (Chase 1981, Chase & Croll 1981). The cephalic tentacles are among the most important prosobranch sense organs, although little attention has been paid to their histologic structure and function. They are richly endowed with sensory cells, which may be significantly different in each of the major groups of gastropods (Haszprunar 1988, Beesley et al. 1998). Ito et al. (2000) stained the neurons in the tentacles in a terrestrial slug, *Limax marginatus*, by backfilling of the tentacular nerves with Lucifer yellow. Four types of stained neurons comprising sensory neurons, gamma cells, ganglion cells, and lateral cells, were identified in the superior and inferior tentacles. In *Haliotis tuberculata*, a temperate species of abalone, the cephalic tentacle has a mixed sensory and motor nerve, which are centrally located and extends along the length of the tentacle. On the periphery of the nerve, there are sinuses located between muscle fibers, and the latter are arranged longitudinally, obliquely and transversely. Covering the muscle is the surface epithelium that is shown to have folds or papillae (Crofts 1929). The epithelium is of cuboidal type, which consists of 3 cell types: sensory cells, supportive epithelial cells, and widely scattered mucus cells. The sensory cells are spindle-shaped with darkly stained nuclei and supporting cells that are oval and more transparent (Crofts 1929, Bevelander 1988). The epipodium is a series of small tentacles arising from the dorsal part of the foot. They often have the same shape and structure as the cephalic tentacles, although they are much smaller (Crofts 1929, Haszprunar 1988). Crofts (1929) in-

dicated that the epipodial tentacles of *H. tuberculata* had 2 types of epithelial cells: supporting cells and sensory cells.

The present study reports on the structure of both the cephalic and epipodial tentacles of *Haliotis asinina* Linnaeus, a tropical abalone commonly distributed along the Thai coastal water, as observed by light and scanning electron microscopes. In addition, immunohistochemistry showed that GABA, a major neurotransmitter of gastropods, is highly concentrated in the sensory epithelial cells.

MATERIALS AND METHODS

Collection of Abalone Specimens

Adult abalones over 12-mo-old were obtained from a land-based culture system at Coastal Aquaculture Development Center, Department of Fisheries, Prachuabkirikun Province, Thailand. They were reared in concrete tanks housed in the shade, and well flushed with mechanically circulated sand-filtered seawater, and provided with an air delivery system to maintain a stable controlled environment. The optimum level of salinity used was ~22.5–32.5 ppt, and the temperature about 22 °C to 26 °C (Singhgraiwan & Doi 1993). They were fed with macroalgae (usually *Gracilaria* spp. and *Laminaria* spp.), supplemented with artificial food.

They were anesthetized in 5% MgCl₂, after which their shells were removed. The tentacles (cephalic, epipodial and appendage) were measured, dissected out and processed for light microscope (LM) and scanning electron microscope (SEM) studies.

Specimen Preparation for SEM

Tentacles were cut and fixed in a Karnovsky fixative (4% glutaraldehyde 2% paraformaldehyde in 0.1M sodium cacodylate

*Corresponding author. E-mail: scewn@mahidol.ac.th.

buffer), pH 7.8, at 4 °C overnight, and washed in 0.1 M sodium cacodylate buffer. They were postfixed in 1% osmium tetroxide in 0.1 M sodium cacodylate buffer for 1 h, at 4 °C. Then, they were dehydrated in graded series of ethanol, and dried in a Hitachi HCP-2 critical point drying machine, using liquid CO₂ as a transitional medium. They were then mounted on aluminum stubs and coated with platinum and palladium in an ion sputtering apparatus, Hitachi E 5000. The specimens were examined in a Hitachi S-2500 scanning electron microscope with an accelerating voltage of 15 kV.

Specimen Preparation for LM

Specimens were fixed in Bouin solution in 0.14 M NaCl for 24 h and washed with 70% ethyl alcohol. They were then dehydrated through a graded series of ethanol, cleared with dioxane, infiltrated and embedded in paraffin. Five-micron-thick sections were cut and stained with Harris hematoxylin and eosin.

For semithin section, specimens were fixed in Karnovsky fixative, pH 7.8, at 4 °C for overnight, and washed with 0.1M sodium cacodylate buffer. They were postfixed in 1% osmium tetroxide in 0.1M sodium cacodylate buffer, at 4 °C, for 1 h. Then, they were dehydrated in a graded series of ethanol and embedded in Araldite 502 resin. Sections were cut at 1- μ m thickness with Porter Blum MT-2 μ L tramicrotome, and stained with methylene blue or PAS-methylene blue. Examination and photographing of the tissue sections were done under a Nikon eclipse E600 microscope and Nikon digital camera DXM1200.

Immunoblotting for GABA

The neural and tentacular tissues were tested for the presence of GABA by homogenizing the cerebral ganglia, pleuropedal ganglia, tentacular, and epipodial tentacles collected from adult *H. asinina* in 0.1 M sodium phosphate buffer saline (PBS) containing 1 mM phenyl-methyl-sulfonyl-fluoride (PMSF). The homogenate was centrifuged at 12000g for minutes, after which the supernatant was collected, and the protein contents determined by Lowry method (Lowry et al. 1951). Proteins were adjusted to be about 1 mg/mL by adding the extraction buffer. A 1- μ L of each suspension at the dilutions at 1:1, 1:10, and 1:100 were spotted onto nitrocellulose (NC) sheets. The NC sheets were then incubated in 5% skimmed milk for blocking of nonspecific binding before being incubated in the primary antibody (mouse monoclonal antibody against GABA, Sigma Chemical Co, USA). Peroxidase-conjugated goat antimouse IgG (Zymed Laboratories) was used as the secondary antibody. The antigen-antibody complexes were then visualized by enhanced chemiluminescence using a LumiGlo kit (KPL, Gaithersburg, MA), with detection made on X-ray film. For positive control neural tissues, the mouse brain was collected and treated similarly.

Immunohistochemistry

Additional 5- μ m sections of paraffin-embedded tentacular and epipodial tentacles, as prepared for LM study, were placed on glass slides, deparaffinized, and rehydrated in ethanol and distilled water. They were then stained by an immunoperoxidase method, by first immersing in 0.1M PBS, pH 7.4, containing 0.3% H₂O₂ to block endogenous peroxidase, followed by 0.1% glycine in buffer to block free aldehyde groups from the fixative, then in 10% normal goat serum in the buffer for 1 h, in monoclonal antibody (MoAb) (Sigma Chemical Co, USA) at 1:300 dilution, at 20 °C overnight. The sections were thoroughly washed with PBS, followed by incubation in HRP-conjugated secondary antibody (Goat antimouse IgG-HRP, Zymed Laboratories) at 1:200 dilution, for 2 h, and labeled with an aminoethyl carbazole substrate kit (AEC, Zymed Laboratories) for 30 min. Finally, the sections were counter-stained with Harris hematoxylin before being mounted in buffered glycerol, and photographed in Nikon eclipse E600 microscope and Nikon digital camera DXM1200.

RESULTS

Cephalic Tentacle

Cephalic tentacles of mature female abalone (age about 16 mo) were 3.77 \pm 0.59 cm in length and 0.14 \pm 0.03cm in diameter (Table 1); whereas the length of cephalic tentacles and the diameters of mature male abalone of similar age was 3.38 \pm 0.57 cm and 0.12 \pm 0.02 cm, respectively. Noticeably, at the same age the female shell was longer than that of male, and its weight was also heavier than that of male (Table 1).

A cephalic tentacle is round and tapered from the base to the tip (Figs. 1A to C). Based on the surface features as observed under SEM, the tentacle could be divided into 3 parts (i.e., 1/10 basal, 1/10 middle and 8/10 top). There are gradual changes between adjacent parts. The basal part has a smooth surface. It consists of many folds, alternated with grooves (Fig. 1E). Many sensory papillae are located on the folds. On the middle part of the tentacle, there are more papillae on each fold (see Fig. 3C). These papillae are distributed separately and appear taller than those at the base. Each appears as a hillock covered with microvilli and encircling cilia at the tip (Figs. 2C, E). On the top part of the tentacle, the papillae are longer and more numerous than those on the middle part (Fig. 1F). Each appears as a slender truncated cone, projecting perpendicularly to the tentacle's surface (Figs. 2A, F). On top of each papilla, there is a tuft of long cilia, whereas the rest of its surface is covered with microvilli (Figs. 2D,F).

In paraffin sections, the longitudinal section of a cephalic tentacle also exhibits the three parts, based on the degree of surface folding that show gradual changes between adjacent parts (Fig.

TABLE 1.
Sizes of cephalic tentacles and epipodial tentacles of adult *H. asinina*.

Sex	Weight (g)	Shell Length (cm)	\pm SD	Cephalic Tentacle Length (cm)	\pm SD	Diameter of Cephalic Tentacle (cm)	\pm SD	Epipodial Tentacle Length (cm)	\pm SD	Diameter of Epipodial Tentacle (cm)	\pm SD
Male	29	3.77	0.62	3.38	0.57	0.12	0.02	0.80	0.24	0.06	0.01
Female	33	4.11	0.64	3.77	0.59	0.14	0.03	0.93	0.32	0.06	0.02

All data are based on 16-mo-old fresh abalone of each sex ($n = 15$). SD, standard deviation.

F. A low-power SEM micrograph of the cephalic tentacle shows the top part of the tentacle that has numerous sensory papillae.

Figure 2. A, A low-power SEM micrograph showing the cone-shaped and knobby surface of an epipodial tentacle that is divided into 3 areas: basal (1), middle (2), top (3) parts. B, A medium-power SEM micrograph of the basal part showing grooves (g) alternating folds (f); the former contain many short papilla (pa). C, A medium-power SEM micrograph of the middle part of cephalic tentacle showing the surface that has short but stout papillae (pa). D, A medium-power SEM micrograph of the papillae (pa) on the top part of a cephalic tentacle, all of which are long and have a cone shape. E, A high-power SEM micrograph of a papilla of the middle part showing a bulbous shape with a tuft of cilia (ci) on top. F, A high-power SEM micrograph of the top part showing many tall cone-shaped papillae (pa) with numerous long cilia (ci) on top, whereas the rest of its surface is covered with microvilli (inset).

3A). Along the axis of each tentacle, there is a central tentacular nerve running along its whole length, and gives rise to the radial branches that innervate the surrounding muscle (Figs. 3B, C). Covering the tentacle is a simple columnar epithelium lying on a thick basement membrane (Figs. 3D, E). The cells in the epithelium covering the papilla can be classified into three types, based on their histologic characteristics and staining affinities. They are: (1) a sensory cell that is spindle shaped with a round or oval shape nucleus, and contains darkly-stained chromatin (Figs. 3D, E). The cytoplasm is dense and stained blue with methylene blue and pinkish purple with PAS-methylene blue. There are long cilia at the tip of each sensory cell, which give rise to the ciliary tuft at the top of each papilla as observed under SEM; (2) a supporting cell which has a columnar or pyramidal shape, and it is generally larger than the sensory cells. It has a round or oval nucleus that contains mostly euchromatin with a few blocks of heterochromatin (Figs. 3D, E). The cytoplasm is clearer than sensory cell, and appears light blue after staining with methylene blue, and light pinkish with PAS-methylene blue stain. The supporting cell has a brush border that is made of microvilli; and (3) a goblet cell, which is a type of mucin-producing cell with a small nucleus and oval shape that is mostly euchromatin (Fig. 3D). The cytoplasm is large, clearer, and stained light blue with methylene blue and pinkish with PAS-methylene blue. At the point where sensory cells aggregate to form a papilla, fibers from the tentacular nerve terminate at a group of these cells that have cilia on top (Fig. 3E).

Epipodial Tentacle

The general structure of an epipodial tentacle is similar to that already described for a cephalic tentacle, but each tentacle is about two times narrower and four times shorter than the cephalic tentacle (Fig. 1A, Table 1). Based on the surface features observed under SEM, each tentacle could also be divided into 3 parts (i.e., 1/5 basal, 1/5 middle, and 3/5 top) (Fig. 2A). Each part has characteristic structures (Figs. 2B, C, D), but there are gradual changes between adjacent parts. The surface of the basal part has folds alternated with grooves (Fig. 2B). On the folds are many short bulbous papillae, each has a circle of cilia on the top (Fig. 2B). In contrast, at the middle part the grooves and folds become less obvious, whereas the papillae are wider and longer, and each appears as a hillock with a circle of cilia on top (Figs. 2C, E). On the top part of an epipodial tentacle there are numerous papillae that are more slender than those on the lower parts, and each appears as a truncated cone with a circle of cilia at the top (Figs. 2D, F).

In spite of its much shorter length, the epipodial tentacle histologically resembles the cephalic tentacle. There are a bundle of epipodial tentacle nerves in the central axis (Figs. 4A, B). Most of surface epithelium, particularly at the basal part of the tentacle, is covered by columnar cells bearing a brush border (Figs. 4C, D). The papilla comprises of three types of epithelial cells with the same characteristics and staining affinities as those of papillae located on a cephalic tentacle (Figs. 4C, D).

Appendage Tentacle

In addition to the cephalic, optic, and epipodial tentacles, *H. asinina* has a pair of vestigial appendage tentacles. Each is short

with a half circle shape, and is covered by numerous irregular folds, alternated with grooves (Fig. 1D). The folds are covered by epithelial cells bearing numerous microvilli.

Transverse sections of the appendage tentacle reveal similar interior structure (i.e., nerve and muscle) to that of the cephalic and epipodial tentacles. The columnar epithelium, which covers the tentacle, also comprises three types of cells that are evenly spread over the surface without being organized into sensory papillae.

Immunoblots of GABA

The extracts of *H. asinina* neural tissues (i.e., cerebral and pleuropedal ganglion) are strongly stained for GABA almost equal to that of mouse brain extract (Fig. 5). However, both tentacular and epipodial tentacular tissues are only slightly stained for GABA.

Sensory Cells Containing GABA

Both of the cephalic and epipodial tentacles have similar patterns of immunostaining for GABA in the cells of epithelium and in the muscle (Fig. 6B). The most prominent immunoreactive cells were sensory cells aggregated at the center of each papilla, which could be readily identified by the presence of cilia on their apical surface (Fig. 6C). Of the remaining surface epithelial cells, the immunoreactive cells are sensory cells, which are widely scattered among the supporting cells (Figs. 6D to F). The nerve bundle and its radiating nerve fibers in both types of tentacles exhibited GABA immunoreactivity (Fig. 6B). In the control the immunostaining is negative (Fig. 6A)

DISCUSSION

Cephalic and Epipodial Tentacles

As in other prosobranch mollusks, the cephalic tentacles of *H. asinina* are the major sensory organs for perceiving the environment conditions because they are the outgrowths from the anterior end of the head (Zaitseva 1997, Beesley et al. 1998). In cross sections the basic structure of the cephalic tentacle is similar to that of other species of *Haliotis* because the tentacular nerve is in the middle of longitudinally orientated muscle fibers, and it is covered by a simple columnar epithelium (Croft 1929, Bevelander 1988, Beesley et al. 1998). In this study, it was found that the epithelium of cephalic tentacles of *H. asinina* has 3 types of cells: sensory cells, supporting cells, which are the majority of cell type, and mucus cells. This is in agreement with the study by Croft (1929) who reported similar finding in the cephalic tentacle of *H. tuberculata*. The sensory cells of the tentacles of *Haliotis* are not sub-epithelial as in pulmonate mollusks (Wright 1974), but are part of the epithelium similar to that in *P. elegans* (Zaitseva 1997). The sensory cells could be easily identified as having oval shaped nucleus with densely stained chromatin and cytoplasm in contrast to the supporting cells that have much clearer nuclei and cytoplasm. In the basal part of the cephalic tentacle, they are widely scattered in the epithelium and are located in the middle and top parts and concentrated in the center of each papilla. Underneath the papilla, there is a nerve branch from the central tentacular nerve bundle that may supply the sensory cells. This situation is similar to the nerve bundles of *P. elegans*, which connect their sensory dendrites to the epithelium of the tentacle tip (Zaitseva 1997). On

Figure 3. Paraffin sections (A to C) and semithin sections (D & E) of cephalic tentacles. A. A low-power LM micrograph of a longitudinal section of cephalic tentacle showing 3 parts: basal (1), middle (2) and top (3). Note the presence of cephalic tentacular nerve bundle (Teb) in the axis of the tentacle. Mu-muscle fasciculus. B & C. A medium-power LM micrograph of a cross section of the basal and top parts, respectively, showing cephalic tentacular nerve bundles (Teb) in the axis. The tentacle is surrounded by an epithelium. E. Mu-muscle fasciculus, pa-papillae, Ten-tentacular nerve. D. A high-power LM micrograph of a semithin plastic section of the top part stained with methylene blue, showing 3 types of cells in the papillae: sensory cell (se), supporting cell (su) and goblet cell (Gb). A group of cilia (Ci) is present on the top of each papillae and linked with the sensory cells, the papillae are more slender and longer than those on the middle part of the tentacle. E. A high-power LM micrograph of a semithin plastic section of the basal part stained with methylene blue, showing an epithelium with brush border (bb). The epithelium contains sensory cell (se), supporting cell (su). Muscle fasciculi (Mu) are seen in the connective tissue underlying the epithelium.

Figure 4. Paraffin sections (A & B) and semithin sections (C & D) of epipodial tentacles. A. A low-power LM micrograph of a cross section of the basal part showing surface epithelium (E) that has few papillae, and a nerve bundle (Epb) in the axis. B. A low-power LM micrograph of a cross section of the top part showing numerous surface papillae (pa) and a nerve bundle (Epb) in the axis. C. A high-power micrograph of interpapillary area of the basal part of an epipodial tentacle stained with methylene blue, showing surface epithelium with brush border (bb), but no papillae. The epithelium consists of goblet cell (Gb), sensory cell (se), and supporting cell (su). The underlying connective tissue contains muscle fasciculus (Mu) and nerve (Epn) to innervate the sensory cells of the epithelium. D. A high-power LM micrograph of the papillae showing sensory cell (se) with cilia (Ci) at the center of a papilla, supporting cell (su) and goblet cell (Gb). The epithelium is covered with brush border (bb).

Figure 5. Chemiluminescent detection of GABA in immunoblots of abalone tissues. Extracts of tissues from cephalic tentacle (HaCe), epipodial tentacle (HaEp), cerebral ganglion (HaCg), and pleuropedal ganglion (HaPPg) were spotted in duplicate onto a nitrocellulose membrane at 0.01, 0.1, and 1 μ g of protein in the extraction buffer. All extracts were positively stained for GABA as well as mouse brain (MB), used as a positive control.

the apical surface of each papilla, SEM showed that there was a bundle of long twisted cilia that in cross section were demonstrated to belong to the sensory cells. In contrast, the supporting cells bear only microvilli that appear in LM as a brush border. The goblet cells are also widely scattered in the epithelium, and few are located in the papilla epithelium. Unlike the epithelium lining the mantle and the hypobranchial gland, the tentacular epithelium is probably not the major site for mucin production because it specializes mostly in the sensory perception.

The epipodial tentacles are smaller and shorter than the cephalic tentacles. They are numerous and located around the foot muscle. They have been shown in this study, as well as in the study by Crofts (1929), to have a basic structure similar to that of the cephalic tentacles. However, the muscle bundles in the epipodial tentacles are smaller and do not appear as regularly arranged as those in the cephalic tentacles. The cephalic tentacles are used for exploring the environment and for seeking out food, while avoiding danger; therefore, they need longer and stronger muscle bundles to stretch and retract them over a long distance. Alternatively the epipodial tentacles function more in support of the cephalic tentacles in finding food and receiving chemical stimuli around the abalone's body. Hence, epipodial tentacles are smaller and shorter than the cephalic tentacles and only project out for a short distance around the body, therefore these tentacles do not need as strong a muscle as in the former.

The group of ciliated sensory cells in the papillae of cephalic and epipodial tentacles are structurally very much like those in the olfactory epithelium or taste buds of vertebrates (Kierszenbaum 2002). Thus, the papillae may function mostly as chemoreceptors similar to the olfactory epithelium and taste buds of the vertebrates. This is supported by many investigators who have shown

that, in addition to tactile reception, the cephalic tentacles also act as chemical receptors because they can respond to the chemical stimuli, odor, and food (Preston & Lee 1973, Farkas & Shurey 1976, Chase 1981, Bell & Tubin 1982, Voss & Schmidt 2001). Shimozono et al. (2001) reported that the metacerebro-procerebral neuron (MPN) of *Limax marginatus* is an output-neuron from the procerebrum. The MPN receives monosynaptic inputs from the superior and inferior tentacle nerves. The MPN, thus, may receive olfactory information via two pathways (i.e., one directly from the tentacle and the others by way of the procerebrum) and possibly functions by integrating both sources of inputs. Similar sensory inputs may be gathered by epipodial tentacles because their papillae have identical structural organization.

Immunohistochemistry

This study has demonstrated the presence of GABA cells of both cephalic and epipodial tentacles. Identification of the immunostained cells is based on the characteristics and the position of cells. These cells are mostly the sensory cells aggregated at the center of each papilla, or single sensory cells widely scattered in the rest of the tentacular epithelium. GABA is the major inhibitory neurotransmitter in the central nervous system and a neuromodulator in certain peripheral tissues vertebrates (Sattelle 1992). In marine invertebrates, GABA is a neurotransmitter that stimulates growth and metamorphosis of the larvae into more mature stage (Aminur & Veharai 2001), and in abalone it specifically stimulates settlement and metamorphosis (Morse et al. 1988) and feeding of larvae (Arshavsky et al. 1993). Therefore, it is highly possible that the GABAergic sensory cells in the papillae of both cephalic and epipodial tentacle play important parts in sensing the availability of food and perhaps also controlling the feeding behavior of the postmetamorphosed abalone up to and during the adult stage.

Appendage Tentacle

The pulmonate mollusks have 2 pairs of tentacles: the superior and inferior tentacles, and the anterior and posterior tentacles, which are called the cephalic tentacle and rhinophore (Beesley et al. 1998). Rhinophores have shapes ranging from simple tapering rods to elaborate lamellae or tubular organs (Beesley et al. 1998). In the prosobranch mollusks, there is one pair of cephalic tentacles, and they do not have a rhinophore (Beesley et al. 1998). In this study, we found a pair of short and small tentacles that had a dome shape and were located dorso-medial to the base of the cephalic tentacle. They were called appendage tentacles. It is possible that these tentacles are homologous to the pulmonates rhinophores, but they remain as vestigial structures. The appendage tentacle has a simple columnar epithelium containing supporting and mucus cells but much fewer sensory cells; there were no papilla like those on the cephalic and epipodial tentacles, and there are no well organized muscles and nerve fibers. Thus, they may just be rudimentary structures.

ABSTRACT The hypobranchial gland of *Haliotis asinina* exhibits major and minor folds that are called leaves and leaflets. When viewed by scanning electron microscope, numerous tufts of rod-shaped cilia, paddle-like cilia, and clusters of granules being exocytosed from the pores were observed on the surface of the leaves and the leaflets. In transverse sections, each of the leaf and the leaflet can be divided into two areas: the basal area consists mainly of two types of large goblet cells, and the apical area that contains a mixture of supporting cells, sensory cells and four types of mucus-secreting cells. *H. asinina* has bipectinate gills. Gills are observed in abalone at the age of 1 mo; and the number and length of their filaments increase with age. In mature abalone, there are about 17 filaments per each gill with equal numbers on both sides. The length of the longest filament is approximately 2.48 mm. Each filament is supported axially by a thin collagenous connective tissue. On the efferent side, there is a V-shaped chitinous skeleton rod. Epithelium lining the filament is composed of tall columnar cells bearing microvilli mixed with ciliated columnar cells and mucus cells.

KEY WORDS: *H. asinina*, gill, hypobranchial gland, histology, SEM

INTRODUCTION

The hypobranchial gland is a single or paired, highly glandular area of the epidermal lining the roof of the mantle cavity (Hyman 1967). Two such glandular areas, one on each side of the rectum, occur in *Haliotis*, and the left one is larger than the right one (Crofts 1929). The hypobranchial gland consists of regular folds or lamellae oriented at right angles to the mantle wall (Hyman 1967). The histology of the hypobranchial gland has been investigated (Crofts 1929, Bevelander 1988). Crofts (1929) described three types of cells in the hypobranchial gland of *Haliotis tuberculata*: mucus cells with spindle shaped secretion, mucus cells with granules, and ciliated cells. Bevelander (1988) described 3 types of cells in the hypobranchial gland of *H. rufescens*: mucus cells with rod-like elements, mucus cells with granular cytoplasm, and supporting cells.

Gills are the principal organs for respiratory gas exchange in mollusks. They are positioned in the mantle cavity (Crofts 1929, Eertman 1996), so they are affected by many substances that flow through the mantle cavity (Schulte-Oehlmann et al. 2000). The studies on gastropod gill morphology is very limited; a few papers have been published on the structure of gills of pulmonate *Siphonaria capensis* (De Villiers & Hodgson 1987) and of some caenogastropod species. The gill structure of the investigated gastropods shows basic uniformity because the gill filaments are composed of a ridge and an extended sheet of nonciliated cells. However, the gill filaments of these various species of gastropods differ in the shape of the filaments (corrugated, triangular, or rounded). Each gill filament is covered with a single layered epithelium of either cuboidal (Schulte-Oehlmann et al. 2000) or columnar cells (Crofts 1929). However, there seems to be a difference in the thickness of the epithelial cells. A hemocoelic space occupies the center of each filament (Eertman 1996, De Villiers & Hodgson 1987). Crofts (1929) found that in *H. tuberculata*, the

V-shaped chitinous skeletal rod, attached to one side of the gill epithelium was similar to that in cephalopoda (Haszprunar 1987). The epithelium of the gill of *S. capensis* and *H. tuberculata* consists of three types of cell: nonciliated cell, ciliated cell, and secretory cell (De Villiers & Hodgson 1987).

To the best of our knowledge, there is still no information on the histology of hypobranchial glands and gills in *H. asinina*, a common abalone species found along the coastal water of Thailand, which is considered to be one of the economic aquatic animals that has been cultured for commercial exploitation. Hence, this study reports on the histology of hypobranchial glands and gills of this species.

MATERIALS AND METHODS

Collection of Abalone Specimens

Abalones were obtained from a land-based culture system at Coastal Aquaculture Development Center, Department of Fisheries, Prachuabkirikun Province, Thailand. They were reared in concrete tanks housed in the shade, and well flushed with mechanically circulated sand-filtered seawater, and provided with an air delivery system to maintain the stable controlled environment. The optimum level of salinity is ~22.5–32.5 ppt, and the temperature ~22 °C to 26 °C (Singhagravan & Doi 1993). They were fed with macroalgae (usually *Gracilaria* spp. and *Laurencia* spp.), supplemented with artificial food.

They were anesthetized in 5% MgCl₂, after which their shells were removed. The gills and hypobranchial glands were dissected out and processed for light microscope (LM) and scanning electron microscope (SEM) studies.

Specimen Preparation for LM

Specimens were fixed in Bouin fluid in 0.14 M NaCl for 24 h and washed with 70% ethyl alcohol. Then, they were dehydrated through a graded series of ethanol, cleared in dioxane, infiltrated

*Corresponding author. E-mail: scewn@mahidol.ac.th

and embedded in paraffin. Five-micron-thick sections were cut and stained with hematoxylin and eosin.

For semithin sections, specimens were fixed in Karnovsky fixative (2% paraformaldehyde and 4% glutaraldehyde in 0.1 M sodium cacodylate buffer, pH 7.8) at 4 °C for overnight, and washed with 0.1 M sodium cacodylate buffer. They were postfixed in 1% osmium tetroxide in 0.1 M sodium cacodylate buffer at 4 °C for 1 h. Then, they were dehydrated in graded series of ethanol and embedded in Araldite 502 resin. Sections were cut at 1- μ m thickness with Porter Blum MT-2 μ Ltramicrotome, and stained with methylene blue or PAS-methylene blue (Hayat 1993). Examination of the tissues sections was done under an Olympus Vanox light microscope.

Specimen Preparation for SEM

Hypobranchial glands were cut and fixed in a Karnovsky fixative (4% glutaraldehyde 2% paraformaldehyde in 0.1 M sodium cacodylate buffer), pH 7.8 at 4 °C, for overnight, and washed in 0.1 M sodium cacodylate buffer. They were postfixed in 1% osmium tetroxide in 0.1 M sodium cacodylate buffer for 1 h at 4 °C. Then, they were dehydrated in graded series of ethanol, and dried in a Hitachi HCP-2 critical point drying machine, using liquid CO₂ as a transitional medium. They were then mounted on aluminum stubs and coated with platinum and palladium in an ion sputtering apparatus, Hitachi E 5000. The specimens were examined in a Hitachi S-2500 scanning electron microscope with an accelerating voltage of 15 kV.

RESULTS

Hypobranchial Gland

The hypobranchial gland of *H. asinina* is located on the dorsal surface of the mantle cavity and runs parallel to the gill. It appears as a large yellow pectinated ridge whose lateral sides are connected to the gills by a thin mantle membrane (Figs. 1A and B, 2A). Each gland consists of many axes, from each of which 8 to 11 leaves arise (Fig. 1B). Under SEM, the major folds or leaves decline from the axis to the lower level and branch into two to three terminals. Many minor folds or leaflets branch off from both sides of each leaf (Fig. 1C). The hypobranchial gland exhibits many tufts of rod-shaped cilia, paddle-like cilia, and granules that are exocytosed from pores on the surface of leaves and leaflets (Figs. 1E and F). In contrast, the junction between the axis and leaf has fewer ciliary tufts, round granules that are being exocytosed from pores on the fold, and there are deep grooves between the folds (Fig. 1D).

In transverse section, each leaf and leaflet can be divided into 2 areas: the basal area, which consists mainly of large mucus cells and the apical area that contains a mixture of supporting cells, sensory cells, and small mucus-secreting cells having goblet appearance (Figs. 2B and C, 3A). These cells have the following characteristics.

1. Supporting cells. These cells vary in shape; they can be triangular, oval, or spindle (Figs. 3B and C). The nucleus is oval and contains mostly pale-stained euchromatin. The upper part of this cell type is wide and shows many long microvilli.
2. Sensory cells. These cells are elongated in shape, and they contain euchromatic oval nuclei with many nucleoli (Figs. 3B and C). The upper part of this cell type is narrow and

reaches the surface of the epithelium where it bears some cilia.

3. Mucus cells. These cells are filled with many mucin granules and have oval shape. Based on the staining characteristics with PAS-methylene blue on semithin sections, there are 4 types of mucus cells (Figs. 3B and C). Type-1 is a mucus cell with a round nucleus and PAS and methylene blue negative granules in the cytoplasm. It is located near the basement membrane (Figs. 3B and C). Type-2 is a mucus cell with flattened euchromatic nucleus and numerous blue granules packed tightly together in the cytoplasm (Figs. 3B and C). Type-3 is a small mucus cell whose cytoplasm is filled with PAS-positive round granules (Figs. 3B and C). Type-4 is the largest mucus cell containing large heterogeneous granules with either pinkish or bluish (methylene blue positive) hues (Fig. 3C).

In the basal area, there are 2 types of mucin cells lying in alternation. Type-1 is the mucus cell, which contain homogenous purple (methylene blue positive) material in the cytoplasm (Fig. 3D). Type-2 is the mucus cell containing homogeneous pale pink (PAS positive) material with streaks of deep pink rod-like materials embedded in the former (Fig. 3D).

Gills

H. asinina has two bipectinate gills, positioned slightly to the left of the center in the mantle cavity and pointing anteriorly (Figs. 1A and B). The gills are attached to the mantle by a thin membrane. There are equal numbers of filaments on both sides (i.e., about 17 filaments per each gill). All filaments lie parallel to each other. Each is a delicate pleat with blunt free tip and is corrugated in the middle (Fig. 4A).

Transverse sections through the gill filaments reveal that they are covered with a single layered epithelium (Figs. 4B to E). Each filament is supported axially by a thin collagenous connective tissue, enclosing the hemocoelic space, which contains hemocytes (Fig. 4E). On the efferent side, there is a V-shaped opaque chitinous skeletal rod (Fig. 4B), serving as the attachment site for muscles that could bring about considerable movement of the gill filament. The gill filament is lined by a columnar epithelium that varies much in thickness in different parts (Figs. 4B to E). Most of the epithelial cells on the proximal and distal ends of a filament are tall columnar bearing microvilli, which appears as brush border under LM, with ciliated epithelial cells (Figs. 4B, C, and E). There are numerous cilia on the region of the apical ciliary band (Fig. 4B) and the lateral ciliary band (Fig. 4C). However, in most of the filaments, the cells are cuboidal and have no cilia (Fig. 4D). Four types of cells can be identified in the epithelium covering the efferent side of the filament (Fig. 4B): (1) the cuboidal cells with round nuclei on the lateral side of the skeletal rod; (2) the ciliated tall columnar cells in the distal end of the filament; (3) the small columnar cells with dense granules and microvilli; (4) the mucus cells with large basophilic or small metachromatic granules in the efferent filament.

The afferent epithelium of the gill filament comprises of 4 types of cells (Fig. 4E). These are: (1) the cuboidal cells with round nuclei with euchromatin and distinct nucleoli on the lateral side; (2) the tall columnar cells with round or oval nuclei located in the terminal epithelium; (3) the ciliated columnar cells in the distal end of the filament; (4) the mucus cell with numerous dense granules packed tightly together in the apical cytoplasm (Fig. 4E).

Figure 1. A & B. Photographs of the dorsal view of the mantle cavity showing the external features of adult *H. asinina* (16 mo old), after removing the shell and dissecting away mantle membrane. ad-adductor muscle, ax-axis, dig-digestive gland, ey-eye, gi-gill, go-gonad, hg-hypobranchial gland, le-leaf, pe-pedal muscle, rt-rectum, te-cephalic tentacle. C. A low-power SEM micrograph of a hypobranchial gland of *H. asinina* showing the leaf (le) which arises from the axis (ax), and leafflets (lf) which branch off from both sides of the leaf. D. Higher magnification of a part on the axis from box 1 in C showing ciliary tuft (ct), secreted granules (gr) and exocytosed pores (p) on the tegumental fold. Notice many deep groove (g) between the tegumental fold. E. A high-power micrograph of a part of the leafflet from box 2 in C, showing numerous ciliary tufts (ct) that are enlarged in the inset, secreted granules (gr) and exocytosed pore (p). F. A nearby area from box 3 in C at the same magnification, showing many paddle-like (pc) cilia that are magnified in the inset.

A survey photomicrograph showing the location of gill (gi) and hypobranchial gland (hg), which are connected by the mantle (mt). d-dorsal, rt-rectum, v-ventral. B and C. Micrographs showing many leaves (le) and leaflets (lf), whose basal (ba) and apical (ap) parts appear to contain mucus cells of distinct characteristics.

DISCUSSION

Hypobranchial Gland

There are some controversies on the types of cells found in the hypobranchial gland. Crofts (1929) and Bevelander (1988) reported 3 cell types in the hypobranchial gland of *Haliotis tuberculata* and *H. rufescens*, respectively. Both authors described 2 types of mucus cells that contain different secretion. Type-1 mucus cell contains rodlike or spindle-shaped secretion while type-2 mucus cell contains granular secretion (Crofts 1929, Bevelander 1988). The third cell type is the supporting cell (Bevelander 1988), which is ciliated (Crofts 1929). These two types of mucus cells correspond to those found in the basal area of hypobranchial gland of *H. asinina*. The first type of mucus cell contains large, rodlike mucin granules that gave an intense positive reaction to PAS, indicating the presence of neutral mucopolysaccharide. In *H. rufescens*, the mucus cell also contains rodlike granules that were identified to be acid mucopolysaccharide in nature (Bevelander 1988). The second type of mucus cell in the basal area of *H. asinina* hypobranchial gland appears homogenous and stains purple with PAS-methylene blue. This may be equivalent to the second type of mucus cell of *H. rufescens*, but the content appears more homogenous in *H. asinina*. Bevelander (1988) suggested that the granules in these cells were glycoprotein.

Figure 3. Semithin cross sections of the leaf of hypobranchial gland stained with PAS-methylene blue. A. A micrograph showing apical part (ap) and basal part (ba) which contain different types of mucus cells and nerve fiber (nf) in the core of the leaflet. B and C. High-power micrographs of the apical part showing supporting cell (su), sensory cell (se) and 4 types of mucus cells: type-1 (1), type-2 (2), type-3 (3), type-4 (4). D. A high-power micrograph of the basal part, showing two cell types of mucus cells lying in alternation; the first cell-type is PAS positive mucus cell (mc_1), and the second cell type (mc_2) methylene blue positive cell.

In *H. asinina*, the apical areas of hypobranchial gland leaves and leaflets represent specialized zones where at least 6 types of cells are formed, (i.e., supporting cell, ciliated sensory cell, and 4 types of mucus cells) whose classification is based on the appearance and staining characteristics of the granules. These mucus cells appear very different from those found in the basal area, both in cell shape and secretion. Judging from the staining pattern to PAS-methylene blue, type-1 and type-3 mucus cells contain neutral mucopolysaccharide granules, whereas type-2 cells contain basophilic granules suggesting acidic protein in nature (Humason 1972). Type-4 mucus cell contains both types of granules, neutral mucopolysaccharide and basophilic granules.

Because of the vast number and considerable variety of mucus cells, the principal function of hypobranchial gland should be the secretion of mucin (Hyman 1967). The surface area of the gland is increased by the folding of the glandular epithelium into large pleats to increase the mucus-secreting area. The quantity of mucus

Figure 4. Photomicrographs of the gill of *H. asinina*. **A.** A micrograph of the gill showing many filaments (fi) aligning parallel to each other. **B.** An enlargement from the efferent end of the filament from box B in Fig. A, showing four types of cells (1-4) in the terminal epithelium which possess both microvilli and short cilia. **C.** A bundle of muscle (mu) is attached to the V-shaped skeletal rods (ro). **C** and **D.** High-power micrographs of the epithelium of the gill taken from boxes C and D in Fig. A, showing many high columnar cells with long cilia in the epithelium near the efferent side and low columnar or cuboidal cells in the epithelium at the middle of the filament. **E.** An enlargement from the afferent end of the filament taken from box E in Fig. A, showing four types of cells in the epithelium (1-4). A hemocyte (hc) is seen in the hemocoelomic space (hs).

discharging into the respiratory chamber increases suddenly if the animal is irritated. Mucus is thus produced and secreted for the protection and for clearing away debris from the anus and renal organs, to keep the gills and mantle cavity clean. Furthermore, when foreign irritating particles from turbid water are attached to the surface of the gland, the mucus cells may release mucus to bind particles that will be brushed away by the ciliary action of the epithelial cells. The mucus cells that perform this function may be type-2 mucus cells because they have similar characteristics to those observed in the gill epithelium that may perform similar function. Crofts (1929) found that irritating oils introduced into the entrance of the respiratory chamber seemed to be perceived at once by the hypobranchial gland, and the shell closed down abruptly, and at once a large amount of mucus was released from the mucus cells. In a similar experiment, Alexander (1970) introduced milk into the respiratory chamber, and obtained similar responses. Furthermore, some mucus cells may release mucin into the seawater, perhaps to clear away the offending substance, as well as to adjust pH of seawater to be suitable for respiration. The mucus cells

participating in this protective action may belong to 2 types (i.e., the acidic and basic mucus cells types-1 and 3). The remaining mucus cell (type-4) may act as general mucus cells that produce mucin to lubricate the organ and protect the gills. Furthermore, the heterogeneity of the mucus cells of hypobranchial gland implies that the secretion of mucin for clearing irritants and debris may not be the only function. The complexity of the mucin released could be involved in other process, such as acting as the inducers for the larval settlement, because it has been shown that mucus trail from adult animals is one of the most important factors for settlement.

Gill

Light microscopic observation shows that the internal structure of the gills and the gill filaments of *H. asinina* have an internal architecture similar to those of other mollusks. The gills are bi-pectinate, with individual filaments showing basic similarities. All filaments are positioned parallel to each other and are linked by a common base through which the hemolymph is directed and distributed to the individual filaments (Eertman 1996). Each filament is corrugated in the middle part, which encloses the hemocoelic space, thus it may be a modification to enlarge the total gill surface area and improve respiratory gas exchange (Crofts 1929, Eertman 1996).

The epithelium of the gills in *H. asinina* is a simple columnar or cuboidal type, which presumably helps to enhance the rapid gas exchange. This feature has been found in most species of mollusks studied so far (Crofts 1929, Eertman 1996, De Villiers & Hodgson 1987). The gill filaments possess areas of ciliated cells alternating with areas of nonciliated cells. In our study, the efferent margin of the filament and both sides of the hemocoelic space in the efferent side consist of ciliated cells (Crofts 1929). Ciliary movement may take part in sweeping mucus secretions from the mucus cells that serve to capture foreign particles and remove them from the gills (Nuwayhid et al. 1978). Hence, the ciliated cells lining the gills observed in the present study may play both roles in making water current and removing irritating particles.

Nuwayhid et al. (1978) did not find any mucus cells in the gills of *Patella vulgata*, whereas in *Siphonaria capensis* there were a larger number of these cells (De Villiers & Hodgson 1987), and in *Anstrocochlea constricta* there were two types of mucus goblet cells (Eertman 1996). The present study revealed two types of mucus cells on the gills of *H. asinina*. All of them are grouped at the efferent and afferent sides of the filament. It was suggested that these mucus cells function primarily in the cleaning of gills by removing dirt in coordination with muscle contraction and ciliary movement (Yonge 1952). The chitinous skeletal rods found in the efferent side may serve for attachment of muscles that bring about considerable movement of the gill filament (Crofts 1929, Haszprunar 1987). In *S. capensis*, it was found that the muscle fibers were located at intervals on the hemocoelic surface (De Villiers & Hodgson 1987). On the contrary, the present study reveals that the muscle fibers are attached to the inner surface of the rod. The function of this muscle may be the same as described earlier.

BIOLOGICAL ZERO POINT IN HYBRID PACIFIC ABALONE

HONGEN ZHAO, JINSHI ZHANG, LIHONG HUANG, AND LIMIN SUN

Dalian Aquatic Products Research Institute, Dalian, 116000 China

ABSTRACT The biologic zero point (BZP) of hybrid Pacific abalone *Haliotis discus hannai* (China) and *Haliotis discus discus* (Japan) at temperatures of 16°C, 20°C, and 22°C was calculated from the developmental hatching rate, formation of larval retractor muscle, 90 degree torsion and formation of epipodial tentacles. BZP for the early development of hybrid Pacific abalone is 6.22°C, which is an important result for the hybrid breeding of Pacific abalone.

KEY WORDS: hybrid, Pacific abalone, biological zero point

INTRODUCTION

Pacific abalone, *Haliotis discus hannai* is a key aquaculture organism, cultivated in China since the 1980s. Commercial seed production commenced in 1987 and, from this time to 1992, abalone aquaculture grew greatly. Most research was focused on development of hatchery seed production techniques and grow-out modes. A series of key techniques involving spawning, larval rearing, and juvenile and seed nursing were established, as well as grow-out systems. Disease and abnormal mortality has recently, however, severely disrupted the industry and promoted the hybridization of *Haliotis discus hannai* (China) and *Haliotis discus discus* (Japan). Hybrid F₁ shows a significant heterosis in survival and growth and is playing an important role in Chinese abalone culture.

A successful culture and high yield are assured by altering rearing conditions at three important stages during larval development: hatching, development of larval shell, and settlement (Hahn 1989). Information on BZP and effective accumulative temperature (EAT) is necessary for the culture of broodstock and hatchery management. BZP is one of the values used to calculate EAT. BZP varies among abalone species, depending on water temperature in each location. The BZP has so far been investigated in seven abalone (Sawateerap et al. 2001) and this study investigates the BZP of hybrid F₁ of Pacific abalone.

MATERIALS AND METHODS

Conditioning of Broodstocks

Mature broodstock of *Haliotis discus hannai* and *Haliotis discus discus*, with a shell length of 8 cm and a weight of 140–180 g, were used. Males and females were separately reared in different nets and placed in 0.7 m³ plastic tanks. Filtered seawater was used and changed daily. Rearing temperature was maintained at 20°C with constant aeration. Broodstock were fed with fresh kelp.

The dietary grazing rate was calculated daily and gonad maturation was determined by size and color according to Ebert and Houk. (1984).

Induced Spawning

Spawning was induced in April 2000. Individuals with mature gonads were chosen for spawning. Female abalone was dried in a shade room (24°C) for 1.5 h, males for 40–60 min. Broodstock were separated, one by one, into 20-L tanks with filtered water irradiated by ultra-violet at 700 mw.L/h. At the same time, abalone for spawning was induced with flow-through seawater at 1–2 L/min and from 24°C to 22°C. Spawning occurred after about an hour.

Artificial Fertilization

Eggs and sperms were collected separately. Eggs were placed in the experimental container at a density of 6 eggs/mL and then maintained at different temperatures (16°C, 20°C, 22°C). Each experiment was performed in triplicate.

Rearing Management

The zygote was washed once every hour with sand-filtered seawater. After hatching, healthy larvae were selected for continued rearing and water was changed every 8 h.

Observation

Larval development was observed microscopically every hour until the epipodial tentacle stage. Development rate of hatch-out, formation of larval retractor muscle, 90 degree torsion and formation of epipodial tentacle were recorded.

Data Analysis

The relationship of rate (t) of larval development and water temperature was $1/t = AT + B$ provides the basis for BZP calculation.

RESULTS

Experiments were repeated three times and data is showed in Table 1.

The BZP was calculated at water temperatures of 16°C, 20°C and 22°C. The average BZP was 6.22°C (Table 2).

TABLE 1.
Developmental rate of hybrid larvae of Pacific abalone at water temperature 16, 20, 22°C.

Group	C	Time of Larval Development (h)			
		Hatch-Out	Larval Reactor Muscle	Torsion (90°)	First Epipodial Tentacle
1	16	17.6	30.9	44.4	87.1
	20	11.8	19.4	31.5	62.5
	22	10.4	19.3	27.4	54.8
2	16	17.7	30.8	44.4	87.1
	20	11.8	20.2	31.5	65.5
	22	10.7	19.8	27.4	54.8
3	16	17.8	31.4	44.4	87.1
	20	12.5	20.0	31.5	64.5
	22	11.5	19.2	27.4	54.8

TABLE 2.

Relationship between water temperature and time on the formation of the fourth larval developmental stage (1/time) and BZP of hybrid abalone.

Larval Development Stage	Equation of Relationship	BZP
Hatch out	$1/t = 0.00604T - 0.0395$	6.54
Larval retractor muscle	$1/t = 0.00340T - 0.0211$	6.21
Torsion (90-degree)	$1/t = 0.00232T - 0.0146$	6.29
Epipodial tentacles	$1/t = 0.00113T - 0.0066$	5.84
Average		6.22

t = hours, T = °C

DISCUSSION

BZP provides the day/hour when larvae are best ready for washing, selection, and settling and is necessary, therefore, for the effective handling of fertilized eggs and larvae in abalone seed production. It also provides a means of obtaining synchronously developed material for this species and presumably others, for developmental, physiologic, ecologic and biochemical investigations.

BZP varies among species, depending on specific geographical location (Table 3). Moreover, the same species in different geographical locations, also has different BZP, hence *H. discus hannai* of Japan is 7.6 °C and *H. discus hannai* of China is 4.2 °C (Zhao 1999).

In this experiment, abalone larvae were reared at different temperatures. From the equation of the relationship between water temperature and time for larval development, we know that the larval growth rate shows large discrepancies at different temperatures. Lower water temperature leads to slower development rate and higher mortality. Water temperature is an important factor in many stages of larval development (Seki & Kan-no 1977). In this study, reared larva were reared at a water temperatures of 13 °C and 14 °C, but the larval mortality was so high that the expected result was not reached. A water temperature of 22 °C is optimum for larval development and, therefore, to reduce mortality and improve larval quality, reared larvae should be transferred as soon as possible to high temperature.

INDUCTION OF GYNOGENETIC DIPLOIDS IN THE SMALL ABALONE, *HALIOTIS DIVERSICOLOR SUPERTEXTA*

MINGYI CAI,^{1,2} CAIHUAN KE,^{1,2,*} ZHIYONG WANG,³ SHIQIANG ZHOU,²
ZHAOXIA ZHANG,¹ YILEI WANG,³ AND ZIPING ZHANG⁴

¹Key Laboratory of Marine Environmental Science (Xiamen University), Ministry of Education, Xiamen, People's Republic of China 361005; ²Department of Oceanography, Xiamen University, Xiamen, People's Republic of China 361005; ³Institute of Aquaculture Biotechnology, Jimei University, Xiamen, People's Republic of China; ⁴Department of Biology and Chemistry, City University of Hong Kong, Hong Kong, People's Republic of China

ABSTRACT The conditions for induction of gynogenetic haploids and restoration of gynogenetic diploids, were studied in the small abalone, *Haliotis diversicolor supertexta*. Gynogenetic diploids were produced by first using chromosome inactivated sperm to fertilize normal eggs and then suppressing the second meiotic division of these eggs. Sperm chromosomes were effectively inactivated with UV irradiation for 50–90 sec at an intensity of 1075 $\mu\text{W cm}^{-2}\text{s}^{-1}$. The decreased capacity of UV irradiated sperm to fertilize eggs could be improved to an acceptable level by increasing insemination concentration of sperm. Eggs fertilized with genetically inactivated sperm developed into abnormal larvae in the haploid state. The diploids were restored when the gynogenetically activated eggs were treated with 0.5 mg l⁻¹ cytochalasin B (CB) for 10 min from 7 min to 17 min post insemination.

KEY WORDS: gynogenesis, abalone, *Haliotis diversicolor supertexta*, UV irradiation

INTRODUCTION

Gynogenesis refers to the development of eggs fertilized by sperm, which genetic material does not contribute to the resulting embryo. Possible applications of the techniques include rapid establishment of inbred lines or strains with high degree of homozygosity, sex-control, and accelerated elimination of recessive deleterious genes from aquaculture population (Arai et al. 1984). Gynogenetic diploids can be obtained by first using chromosome inactivated sperm to fertilize normal eggs and then suppressing the first or second meiotic division of these eggs or the first mitotic division of the zygotes.

In molluscs, studies on gynogenesis were preliminary, and the progress was slow. Arai et al. (1984) first studied on the conditions of inactivating sperm by ultraviolet ray (UV) in *Haliotis discus hannai*. After 6 y, Fujino et al. (1990) induced gynogenetic diploids in *Haliotis discus hannai* by cold shock treatment of zygotes after insemination with UV-irradiated sperm, which resulted in 50% to 60% gynogenetic diploid in 6-mo-old individuals proved by the analyses of isozyme genotypes. In the pearl oyster *Pinctada martensii*, Xu et al. (1990) produced high levels of gynogenetic embryos, but did not report the production of viable postlarval gynogens. In the Pacific oyster *Crassostrea gigas*, Guo et al. (1993) produced gynogenetic diploids using cytochalasin B (CB) treatment of zygotes after insemination with UV-irradiated sperm. Guo and Gaffney (1993) observed the growth of the 10-mo-old surviving individuals of the gynogenetic Pacific oyster. Gynogenetic diploids several weeks old have also been reported in *Mytilus edulis* (Fairbrother 1994) and *Mytilus galloprovincialis* (Scarpa et al. 1994).

Small abalone, *Haliotis diversicolor supertexta*, is one of most important abalone species cultured in China, especially in southern China. Reports concerning the induction of triploids in the small abalone have been published (Yan et al. 1999, Yan & Chen 2002, Yang et al. 1998), whereas studies concerning the technique of induction of gynogenesis in the small abalone have not been re-

ported. Therefore, the purpose of this work is to establish the procedure to induce gynogenetic diploids in the small abalone.

MATERIALS AND METHODS

Gamete Preparation

Samples of sexually matured *H. diversicolor supertexta* (introduced from Taiwan) were obtained from Dadeng Abalone Hatchery near Tongan Gulf, Xiamen, China. Spawning of gametes was artificially induced by stimulation with air exposure and UV-irradiated seawater. The concentration of the sperm stock solution was determined using a hemocytometer under a microscope. Eggs were rinsed with 0.22- μm membrane filtered sea water, and allotted into 20- μm screens, 2,000–5,000 eggs per screen, ready for fertilization. The following experiments were carried at 22°C to 23°C.

Inactivation of Spermatozoa

To determine optimal UV dosage, sperm was exposed to UV irradiation for various durations. The UV source was two 15-watt germicidal lamps (wave length: 254 nm). Before irradiation, the UV lamps were warmed up for stabilization. Sperm suspension at a concentration of 5×10^6 sperm mL⁻¹ was layered onto the Petri dish on a shaker to form a thin layer of 1-mm depth, and exposed to the UV light for varying duration from 0 sec to 90 sec. Sperm suspension was shaken at a speed of 40 cycle min⁻¹ (THZ-C, Taichang, China) when exposed to UV irradiation. The distance between the lamps and the dish was adjusted to 17.5 cm. At this distance, the intensity of UV was measure as 1075 $\mu\text{W cm}^{-2}\text{s}^{-1}$ (UV-B, Handy, China).

After irradiation, 2-mL sperm solution was immediately mixed with eggs in 50 mL sea water. A portion of eggs to which sperm suspension had not been added was used as a blank control to monitor the contamination of normal sperm. At 8 min postinsemination (p.i.), the zygotes were rinsed with membrane filtered sea

water and then incubated at 22°C to 23°C. Each group was triplicated in the experiment.

Fertilization rate were calculated by counting the cleaved egg at 1.2 h p.i., and survival rate and normality rate were estimated at 28 h p.i. by examining the morphologic appearance and swimming behavior of larvae. The ploidy of trochophores from each group was determined by chromosome counts in accordance with Li et al. (2000a). The chromosome number of diploid in the small abalone is 32 (Arai et al. 1998).

Optimization of the Insemination Concentration of UV Inactivated Sperm

Results of preliminary experiments indicated that sperm's abilities of motility and fertilizing the eggs were significantly reduced with increasing UV dose, but the fertilization ability could be compensated by improving insemination concentration of sperm. Because 50–90 sec UV irradiation at $1.075 \mu\text{W cm}^{-2}\cdot\text{s}^{-1}$ inactivated sperm effectively, the insemination concentration of sperm

Figure 3. Ploidy of trochophores resulting from fertilization when sperm were exposed to UV irradiation of $1075 \mu\text{W cm}^{-2}\cdot\text{s}^{-1}$ for various duration.

was optimized from 50, 70, 90, and 120 sec irradiation groups in this experiment. The irradiated sperm were mixed with normal eggs with varying insemination sperm concentrations of 5.0×10^4 , 2.5×10^5 , 7.5×10^5 and 1.25×10^6 sperm mL^{-1} . Cleavage of eggs was determined at 1.5 h p.i. Hatching and normality rates in trochophores were determined at 10 h p.i. Chromosome counts were conducted as earlier mentioned.

Production of Gynogenetic Diploids

There were five groups in this experiment. The first group was a blank control group (BC group), in which eggs to which sperm had not been added, were used to monitor the contamination of normal sperm. The second group was the gynogenetic haploid group (G-n group), in which eggs fertilized by inactivated sperm were allowed to develop to haploids without further treatment. The third group was the gynogenetic diploid group (G-2n group), in which gynogenetically activated eggs were treated with CB for chromosome doubling. The fourth group was the normal diploid

Figure 2. Morphology of normal diploid A, and abnormal haploid B, veligers of *H. diversicolor supertexta* measured at 16 h post insemination.

Figure 4. Metaphase plates from haploid A, aneuploid B, diploid C, and triploid D trochophores of *H. diversicolor supertexta*.

group (N-2n group), in which eggs were fertilized with normal sperm without further treatment. The fifth group was normal triploid group (N-3n group), in which eggs were fertilized with normal sperm and treated with CB. This experiment was carried out at 28.6°C. Each treatment was triplicated.

In gynogenetic groups, sperms were exposed to 75 sec UV irradiation based on the results of earlier experiment. Irradiated sperms and normal sperms were used to fertilize eggs with sperm

concentrations of 1.25×10^6 and 5.0×10^7 sperm mL^{-1} respectively. The method for chromosome doubling was conducted according to Yan et al. (1999) with slight modification as follows. The eggs were exposed to 0.5 mg l^{-1} CB (in seawater with 0.033% DMSO) for 10 min. CB treatment started when the first polar body appeared in 50% of the eggs, judged by microscopic examination (7 min p.a. in gynogenetic group, 6 min p.a. in normal group). After CB treatment, the eggs were immersed into seawater (with 0.033%

DMSO twice, for 10 min each time, to remove residual CB. Fertilization, hatching, normality rate, and ploidy state were estimated as earlier.

RESULTS

Inactivation of Sperm Chromosomes

The relationship between the duration of UV irradiation and fertilization rate of eggs, survival rate, and normality rate of zygotes at 28 h p.i. is shown in Figure 1. The fertilization rate was 100% for the 0 sec group, and did not decline apparently less than 60 sec irradiation, whereas the rates of survival and normal development of veliger decreased sharply with the increase of UV irradiation. Various kinds of abnormal larvae (Fig. 2b) presented in UV treated groups (e.g., no shell, no velum, small body, disassembled, or agglomerated) whereas the normal larvae (Fig. 2a) that developed into veligers possessed the velum and shell.

The percentage of diploids dropped sharply with increasing duration of irradiation and reached zero by 20 sec irradiation (Fig. 3). A peak of aneuploid formed in short term irradiation groups (4–8 sec) and declined with prolonged irradiation. The percentage of haploid and subaneuploid (chromosome number less than 16) increased steadily and reached 100% by 50 sec UV irradiation. Declining chromosome numbers in the cells of aneuploids were also found. Mitotic metaphase plates from the trochophore cells of *H. diversicolor supertexta* are shown in Figure 4. Dicentric, trivalent, bridged, and fragmental chromosomes occurred in high frequency in the groups of 12–20 sec irradiation.

Insemination Concentration of Inactivated Sperm

The fertilization rates could be improved by increasing the insemination concentration of genetically inactivated sperm (Fig. 5) and reached 100% for 50- and 70-sec groups and 86% for the 90 sec. group, but the sperm from the 120-sec group could not activate eggs even with 12.5×10^5 sperm ml^{-1} . The increase of insemination sperm concentration did not influence the ploidy state of the treatment groups (Table 1). No normal larvae were observed in any treatment groups in this experiment.

Production of Gynogenetic Diploid and Normal Triploid

The fertilization and hatching rate in all treatment groups were high (Table 2). The morphologic normality rate of trochophores was 0% in the G-n group, and increased to 76.6% with CB treatment in the G-2n group.

The distributions of chromosome numbers in trochophore cells from the treatment groups are shown in Figure 6 and the karyological data are presented in Table 3. In the G-n group, diploids were undetectable, 18.8% subaneuploid, 56.3% haploids, and 25.0% aneuploid with low chromosome number (17–21) were observed, which indicated that the UV treatment of sperm, used in this experiment, effectively destroyed the integrity of the sperm genome.

The CB treatment successfully doubled the chromosome number in the G-2n and N-3n groups. In the G-2n group, among the cells observed, 38.6% were diploids, 11.4% were triploids, 4.5% were tetraploids, and 45% were aneuploids with various chromosome numbers (Table 3). No haploid were detected in the G-2n groups. In the N-3n group, 54.8% triploids were produced, 6.5% remained as diploids, and 38.7% were aneuploids.

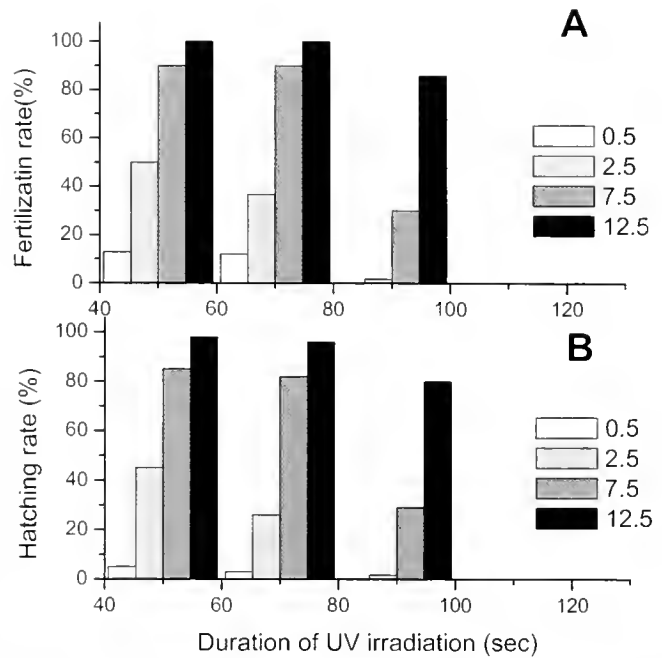

Figure 5. Fertilization rates A, and hatching rates B, of eggs after fertilized with inactivated sperm at various concentration, with various dose of UV irradiation. 0.5, 0.5×10^5 sperm ml^{-1} ; 2.5, 2.5×10^5 sperm ml^{-1} ; 7.5, 7.5×10^5 sperm ml^{-1} ; 12.5, 12.5×10^5 sperm ml^{-1} .

DISCUSSION

Inactivation of Sperm

UV has been used to inactivate sperm chromosomes for gynogenetic induction in many species of molluscs. The dosage of UV irradiation for inactivating the genetic material of sperm varies among species: 30–60 sec of $42 \text{ erg m}^{-2}\text{s}^{-1}$ in *H. diversicolor hannai* (Arai et al. 1984), 120 sec of $4 \mu\text{W cm}^{-2}\text{s}^{-1}$ in *P. martensii* (Xu et al. 1990), 5–6 min of $1,080 \mu\text{W cm}^{-2}\text{s}^{-1}$ in *C. gigas* (Guo et al. 1993), 2 min of $620 \mu\text{W cm}^{-2}\text{s}^{-1}$ in *Mytilus galloprovincialis* (Scarpa et al. 1994), and 50–60 sec of $720 \mu\text{W cm}^{-2}\text{s}^{-1}$ in *Patinopecton yessoensis* (Li et al. 2000b). The optimal dosage of UV irradiation is that which effectively destroys the sperm chromosomes, but does not significantly reduce the ability of sperm to activate eggs. In this study, the results of chromosome counts and fertilization rate determination showed that 50–90 sec UV irradiation of $1075 \mu\text{W cm}^{-2}\text{s}^{-1}$ could effectively inactivate the sperm chromosome but leave the sperm able to activate the eggs of the small abalone.

TABLE 1.

Percentage of haploid and subaneuploid in trochophores increased with UV irradiation dosage ($P < 0.001$) and were not influenced by insemination sperm concentration ($P = 0.44$).

Concentration (cells ml^{-1})	Percentage of Haploid and Subaneuploid Observed			
	50 sec	70 sec	90 sec	120 sec
0.5×10^5	93.2	100.0	100.0	—
2.5×10^5	92.4	100.0	100.0	—
7.5×10^5	90.6	100.0	100.0	—

Data were analysed by Two-way ANOVA using SPSS version 12.

TABLE 2.

Fertilization, hatching and normality rates of eggs/zygotes in the experimental groups.

Group ^a	FR (%)	HR (%)	NR (%)
BC	0.0 ± 0.0	—	—
G-n	97.7 ± 1.5	99.3 ± 0.6	0.0 ± 0.0
G-2n	99.3 ± 0.6	97.8 ± 1.7	76.6 ± 1.5
N-2n	98.6 ± 1.1	99.6 ± 0.6	89.7 ± 0.6

Combining the results of ploidy analysis and insemination sperm concentration optimization, 75 sec UV irradiation of $1.075 \mu\text{W cm}^{-2}\text{s}^{-1}$ was used in the production of gynogenetic diploids in this study. Although 75 sec UV irradiation did not destroy all of the sperm chromosomes as aneuploids remained in G-n group, it affected the genomic integrity of all. Aneuploids were also observed in the gynogenetic haploid group in *C. gigas* (Guo et al. 1993, Li et al. 2000c). Aneuploids, and undetectable chromosome fragments in haploids, may be an important reason for low viability of gynogens in fish (Thorgaard 1983, Ihssen et al. 1990). More detailed optimization of the dosage of UV irradiation, based not only on fertilization rate and the proportion of haploid but also on the viability of gynogens in larval and postlarval stages, would inactivate sperm chromosome more completely and possibly make gynogens more viable.

In some reports, fertilization rates decrease with an increasing dose of UV irradiation (e.g., Arai et al. 1984, Li et al. 2000c), whereas in other reports, fertilization rate decreased only after a threshold dose of irradiation (e.g., Guo et al. 1993, Fairbrother 1994). In the present study, fertilization rate decreased significantly only after irradiation for more than 50 sec at the insemination sperm concentration of 2.0×10^5 sperm mL^{-1} , whereas the fertilization rate kept decreasing at a lower insemination sperm concentration (Cai, unpublished data). On the other hand, the decreased fertilization rate could be improved to a higher level by increasing insemination sperm concentration (Fig. 5). This allowed a relative larger dosage of UV irradiation to be used for inactivating sperm chromosomes more completely.

Chromosome Doubling

CB is the most commonly used to induce "chromosome-doubling" for induction of triploids and gynogenetic diploids in molluscs (e.g., Guo et al. 1993, Yan et al. 1999, Li et al. 2000c). CB treatment also doubled the chromosome successfully in this study (Fig. 6). The normality rates were 0% when the sperm were exposed to UV irradiation for more than 30 sec, whereas it increased to 76.6% after CB treatment. A total of 75.1% cells with less than 16 chromosomes were observed in G-n group, whereas 54.5% with more than 32 chromosomes were observed in the G-2n group. Triploids also showed the chromosome doubling.

The starting time of CB treatment is determined by the developmental speed of the early embryo. Allen and Bushek (1992) recommended the time when 50% Pb I appeared in activated eggs as the starting time of CB treatment to block Pb II in the Pacific oyster. The starting time of CB treatment for chromosome doubling in this study was determined by microscopic observation

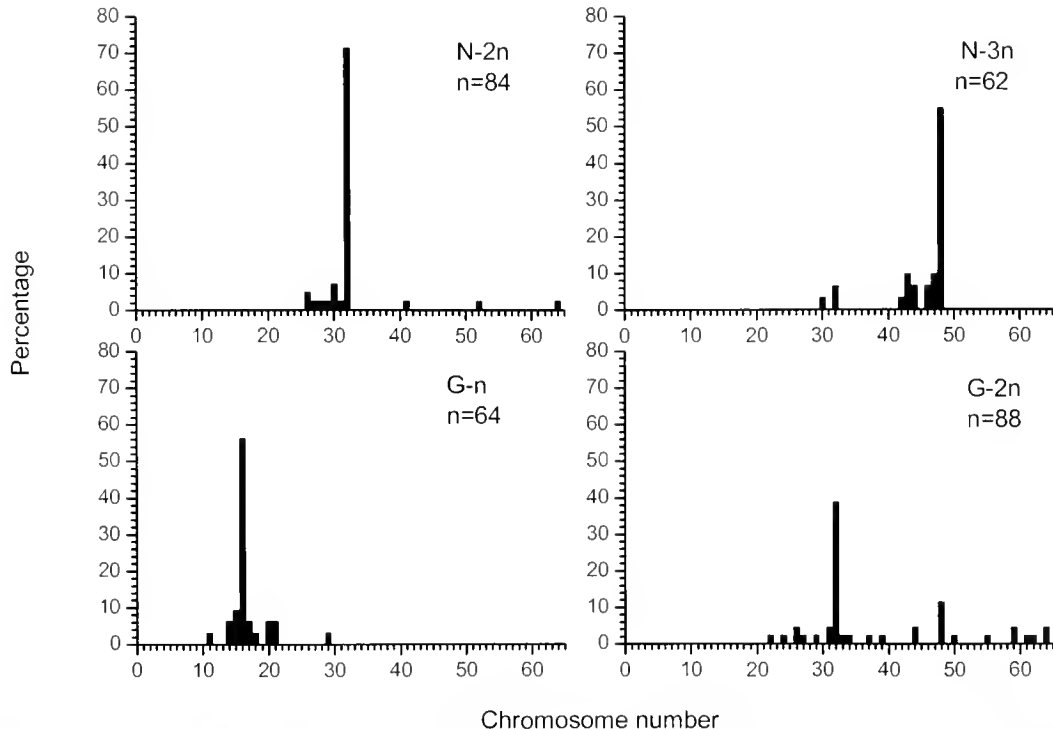

Figure 6. Distributions of chromosome counts in trochophores from various groups. G-n, gynogenetic haploid group; G-2n, gynogenetic diploid group; N-2n, normal diploid group; N-3n, normal triploid group.

TABLE 3.

Levels of euploid (chromosome number) and aneuploid (chromosome number) produced in gynogenetic haploid group (G-n), gynogenetic diploid group (G-2n), normal diploid group (N-2n) and normal triploid group (N-3n)

Groups	Percentage of Ploidies Observed							
	Aneuploid (<16)	Haploid (16)	Aneuploid (17–31)	Diploid (32)	Aneuploid (33–47)	Triploid (48)	Aneuploid (49–63)	Tetraploid (64)
G-N	18.8	56.3	25	0.0	0.0	0.0	0.0	0.0
G-2n	0.0	0.0	18.2	38.6	13.6	11.4	13.6	4.5
N-2n	0.0	0.0	23.1	71.8	2.6	0.0	0.0	2.6
N-3n	0.0	0.0	3.2	6.5	35.5	54.8	0.0	0.0

according to the biologic criteria recommended by Allen and Bushek (1992). The starting time in the G-2n group was later than that in the N-3n group, which was ascribed to the slower developmental progress in comparison with that of normal fertilized eggs (Li et al. 2000a).

Triploids, tetraploids, and aneuploids produced in the gynogenetic diploid group were reported also for the Pacific oyster (Guo et al. 1993, Li et al. 2000c). In this study, the standard deviation of chromosome numbers in G-2n group was much larger than twice of that in G-n group (Fig. 6). The possible reasons for the production of triploids, tetraploids, and large numbers of aneuploids were nonsynchronous development of eggs or inappropriate starting time of CB treatment, which resulted in blocking the release of Pb I, Pb II, or both Pb I and Pb II among eggs. Although chromosome doubling has been successfully induced in this study, further optimization of the starting time, based on ploidy analysis and viability, would improve the yield and quality of gynogens.

The restoration of diploids, determined by karyotyping or flow cytometry, was used to identify the success of genetic induction in fish and molluscs (Guo et al. 1993, Colombo et al. 1995, Li et al. 2000c). In this study, karyotyping was used to monitor the restoration of diploid in genetic induction in the small abalone. Chromosome loss is very common in chromosome preparation, so there

were only 71% diploids in normal diploid group in this study, others being represented as aneuploids after artificial chromosome loss. Because the deviation of the chromosome number from the true one was limited such as in N-2n group, and the majority of distribution of chromosome of chromosome-doubling treatment group could separate from that of no-doubling treatment group (Fig. 6), chromosome counts used in this study still could be used to identify gynogenesis indirectly. The true assessment of the small abalone with exclusively maternal inheritance could only be demonstrated by using biochemical or molecular genetic maker, which was difficult to carry out in larval stage.

Records of viable gynogens in 10-mo-old *C. gigas* (Guo & Gaffney 1993) and in 7-mo-old *H. discus hamai* (Fujino et al. 1990) indicate that it is possible to apply this technique in genetic improvement programs. Studies on the performance of gynogenetic diploids of *H. diversicolor supertexta* are now in progress at our laboratory.

POLYETHYLENIMINE PROMOTES SPERM-MEDIATED TRANSGENE AND OLIGONUCLEOTIDE DELIVERY IN ABALONE *HALIOTIS DISCUS HANNAI*

ABSTRACT In this study, a pCMV2-EGFP plasmid (Invitrogen), in which the enhanced green fluorescent protein gene under the control of the CMV2 promoter, was used as a reporter gene to evaluate the efficiency of the gene transferring techniques into Pacific abalone *Haliotis discus hannai*. The GFP reporter gene was transferred into abalone eggs with four methods: microinjection method, sperm vector method, polyethylenimine (PEI) method and polyethylenimine-mediated sperm-vector (PEI-SV) method. The results indicate that the PEI-SV method is more efficient and convenient in gene delivery into abalone eggs compared with the microinjection method and the conventional sperm vector method. A significant proportion (13.9%) of the fertilized eggs developed normally into blastomeres and expressed green fluorescent protein at high level after gene transfer with the PEI-SV method, and 7.6% of them survived to the trochophore stage. PCR analysis suggests that the mechanism of PEI-SV gene transfer method was that PEI/DNA was taken up by spermatozoa and carried into eggs during fertilization. In addition, PEI-mediated transport of FAM-labeled 10 mer oligonucleotide into abalone sperm cells resulted in almost 100% bright fluorescent nuclei. The PEI-SV gene transferring method can be an effective tool to transfer gene into other animal species.

KEY WORDS: polyethylenimine, gene transfer, microinjection, sperm, abalone, *Haliotis discus hannai*

INTRODUCTION

Abalone is a valuable marine shellfish with great economic importance in marine aquaculture. *Haliotis discus hannai* is the major commercial abalone species in the northeast coastal area of China. Because abalone grow very slowly, it generally takes 3–4 y of farming from seeding to harvesting, which greatly limits the productivity of abalone aquaculture. Transfer of growth hormone gene is a possible way to breed fast-growing abalone. Research on transgenic abalone is far from successful because of many difficulties in gene transferring technologies. One of the most intractable obstacles is the lack of a suitable method to transfer foreign genes into fertilized abalone eggs.

The first successful transfer of a rat growth hormone gene, under a metallothionein promoter, into a mouse, resulted in a dramatic increase in growth. This was performed using a microinjection method (Palmiter et al. 1982, Palmiter et al. 1983). Since then several other techniques for gene transfer such as sperm vector, electroporation, high-velocity microprojectile bombardment, and sperm electroporation, have been developed. None of these methods are appropriate for transferring foreign genes into marine shellfish species. Because of the high mortality of fertilized eggs and larvae, millions of fertilized eggs must be transferred to ensure the production of transgenic shellfish. Microinjection is still a general method with acceptable efficiency in transferring gene into most animal species. However, it is almost impossible to produce transgenic shellfish with the microinjection method. Generally, micromanipulation cannot produce enough embryos due to the difficulties of skills, the length of time required, and high mortality of the injected eggs. The ease of artificial fertilization of shellfish enables the use of sperm electroporation, a powerful tool for increasing efficiency and number of transgenic embryos. Although high gene transfer efficiency has been reported (Powers et al. 1995), sperm electroporation, as well as microinjection, are difficult to control, demand high skill levels, and are time-consuming methods, which limit their application to shellfish.

To enhance the efficiency and overcome the difficulties in transgenic shellfish research, a new gene transfer method—polyethylenimine-mediated sperm-vector (PEI-SV) is proposed and evaluated by transferring a green fluorescent protein reporter gene into the Pacific abalone, *Haliotis discus hannai*.

MATERIALS AND METHODS

Abalone

Mature male and female parental Pacific abalone *Haliotis discus hannai* individuals were obtained from Rongcheng Xunshan Abalone Hatchery in Shandong Province. After the ovulation or sperm ejaculation of the parental abalone, eggs and sperm were mixed together for fertilization when needed. The density of the eggs and sperm was controlled at approximately 1:10,000 to gain a high fertilization rate. The fertilized eggs were washed with filtered seawater 20 min after fertilization to remove excessive sperm and prevent them from decaying.

The Reporter Gene

A pCMV2-EGFP plasmid (Invitrogen) in which the enhanced green fluorescent protein gene was under the control of the CMV2 promoter, was used as a reporter gene to evaluate the efficiency of the gene transfer techniques. *E. coli* DH5 α was transformed with the pCMV2-EGFP plasmid. The expression of the green fluorescent protein gene in *E. coli* DH5 α was visualized through a fluorescent microscope. The plasmid was then propagated and extracted. Fifty μ g of the circular pCMV2-EGFP plasmid was cut with restriction enzyme EcoR I, purified with a plasmid purification kit (SANGON) and dissolved in 500 μ L of DW₂ for use.

The PEI/DNA Complex

Forty μ g of the linear pCMV2-EGFP plasmid DNA was diluted into 2 ml of DW₂. PEI vector was used at 1:1 PEI/DNA ratios (W/W). The desired amount of 25-kDa polyethylenimine (Sigma) was added to the plasmid solution, mixed, vortexed, spun down, and incubated at room temperature for 10 min before use.

Gene Transferring

The experiment was designed in 5 groups: control group, microinjection group, SV group, PEI group, and PEI-SV group. The control group consisted of about 50,000 fertilized eggs, without any treatment. The development of fertilized eggs was observed microscopically and expression of GFP was monitored with an Olympus fluorescent microscope. All experiments were done in duplicate. The fertilization and survival rates were calculated for each group at 1 h and 16 h after fertilization, when the fertilized eggs began the first cleavage and became trochophores respectively. The expression of the GFP was monitored with fluorescent microscopy through the developmental process of the embryos from 1 to 6 h after fertilization.

Microinjection Group:

The reporter gene was transferred with the microinjection method. Two μg of the linear pCMV2-EGFP plasmid was diluted with microinjection buffer (7 mM Tris, 0.15 mM EDTA, pH 7.0) to a final concentration of 2 $\mu\text{g}/\text{mL}$. Fertilized eggs were taken from the control group and 500 eggs were injected with 0.02 μL *P_{CMV2-egfp}* solution for each (Fig. 1A). Microinjection was performed using a Nikon micromanipulation system.

SV Group:

About 10,000 eggs were transferred with the conventional sperm-vector method. Four μg of the linear plasmid pCMV2-EGFP was diluted to 2 $\mu\text{g}/\text{mL}$ with DW₂, and mixed with the sperm at 1:50 volume ratio. The sperm/DNA mixture was incubated at room temperature for 10 min and mixed with the eggs for fertilization.

PEI Group:

About 10,000 eggs, taken from the control group, were transferred with the reporter gene using PEI as vector. The DNA/PEI mixture with 4 μg of DNA was mixed with fertilized eggs at a 1:50 volume ratio, 10 min after fertilization.

PEI-SV Group:

About 10,000 eggs were transferred with the PEI-mediated sperm-vector method. The DNA/PEI mixture with 4 μg of the linear plasmid DNA was added to the sperm at 1:50 volume ratio and gently mixed with a pipette. The sperm/DNA/PEI mixture was mixed with the eggs for fertilization immediately, by which the DNA/PEI complex was transferred into the eggs.

PCR Analysis of the GFP Reporter Gene

Polymerase Chain Reaction (PCR) technology was used to testify whether PEI can carry DNA into abalone sperm cells or not. Three sperm/PEI/DNA mixture samples were washed with DW₂ and sperm was collected after centrifuging three times to remove DNA molecules attached to sperm surfaces. Then DNA was extracted with Genomic DNA extraction kit (Sangon) and tested with PCR technology using a pair of GFP gene specific primers: P1: 5'-CCAACACTTGTCACTACTTT-3', P2: 5'-GCTTTGATTCATTCTTT-3'. DNA extracted from normal abalone sperm and sperm/DNA mixture was used as a negative control, and plasmid DNA was used as a positive control. The PCR reactions were performed in a total volume of 20 μL , using 100 nM of each primer, 200 mM dNTPs, in 1X PCR Buffer supplemented with MgCl₂ at a final concentration of 1.5 mM. The amplification was carried out on a MJ PTC-100 thermal controller as follows: a 2 min predenaturing at 94 °C, followed by 30 cycles (30 s at 94°C, 1 min

TABLE 1.

Fertility rate, survival rate and GFP expression data in each group (%).

Group	Total Number	Fertilization (%)	Survival (%)	GFP Expression (%)
Control	50,000	97.4	83.6	0
Microinjection	500	97.4	0	0
SV	10,000	95.2	82.3	0
PEI	10,000	97.4	52.7	3.8
PEI-SV	10,000	16.3	7.6	13.9

30 s at 60°C, and 3 min at 72°C). The reaction was completed by a final extension step at 72°C for 5 min, then electrophoreses on a 1.5% agarose gel for 30 min at 5V/cm and visualized with UV light after EB staining.

Transferring Fluorescent Labeled Oligonucleotides

Five µg of FAM-labeled 10 bp random sequence oligonucleotides were diluted into 200 µL of DW₂, PEI vector and used at 1:1 PEI/DNA ratios (W/W). The desired amount of 25-kDa polyethylenimine (Sigma) was added to the plasmid solution, mixed, vortexed, spun down, and incubated at room temperature for 10 min. Then the FAM-labeled oligonucleotides and the PEI/oligonucleotides mixture was added to the sperm cells, mixed, vortexed, spun down, and incubated at room temperature for 60 min. The sperm was mixed with eggs for fertilization, and then the sperms and the eggs were observed through fluorescent microscopy.

RESULTS

Fertility, Embryo Survival, and Expression of GFP

The fertilization rate, survival rate and the GFP expression rate for each group is shown in table 1. In the control group, 97.4% of the fertilized eggs cleaved, and 83.6% of them survived to the trochophore stage. The fertilized eggs used in the microinjection group were taken from the control group, so the fertility rate was also 97.4%. However, none of the 500 injected fertilized eggs cleaved 1 h after fertilization. Fluorescent microscopy revealed that none of them expressed GFP at 5 h after fertilization.

In the SV group, 95.2% of the fertilized eggs cleaved and 82.3% of them survived to the trochophore, but none of them expressed GFP. In this study, the conventional sperm vector method did not decrease the fertilization rate and the survival rate, yet it did not deliver GFP gene into the fertilized eggs successfully either. In PEI group, the fertilized eggs were also taken from the control group, so the fertility rate should also be 97.4%, whereas the survival rate to trochophore was only 52.7%, which was significantly lower than that of the control group. Fluorescent microscopy revealed 3.8% of them expressed GFP and a small proportion (less than 5%) of them expressed GFP in mosaic manner (Fig. 1B).

In the PEI-SV group, only 16.3% of the fertilized eggs cleaved by 1 h after fertilization, and 7.6% of them survived to trochophores by 16 h after fertilization. The fertilization rate and survival rate was significantly lower than the control group. The

gene delivery efficiency was, however, significantly higher than the other groups: 13.9% of the fertilized eggs developed into blastomeres and expressed GFP at high level, at 5 h after fertilization (Fig. 1C). Compared with the PEI group and the SV group, it is obvious that PEI promotes the sperm-mediated gene delivery into the abalone eggs.

PCR Analysis of the GFP Reporter Gene

PCR technology was used to test whether PEI could carry DNA into sperm cells or whether it was attached to the cell membrane. The sperm/PEI/DNA mixture was washed three times with clean seawater and the sperm DNA was extracted and amplified with GFP gene specific primers. For all 3 samples tested, the strong PCR bands showed that the PEI/DNA complex did carry DNA into the sperm cell, or the complex attached to the cell membrane that cannot be washed off with water. The negative controls amplified with DNA extracted from normal sperm cells or sperm cell mixed with DNA without PEI treatment, showed no bands, indicating that the sperm cells did not absorb DNA by itself or DNA was degraded by nuclease without the protection of the PEI/DNA complex.

PEI Carried Oligonucleotides to Sperm Cells

Generally short oligonucleotides do not require a carrier to enter a cell through fluid-phase endocytosis. However lysosomal degradation remains a problem. Polyethylenimine has been shown to help oligonucleotides to reach their nuclear target (Boussif et al. 1995). We therefore tried PEI for carrying oligonucleotide into abalone eggs. In the control experiments, abalone sperm cells were incubated with FAM-labeled 10 mer oligonucleotide (10 µM) for 2 h, then rinsed and fixed. Fluorescent microscopy did not reveal any remaining cell-associated oligonucleotide or nucleoside, which may be a consequence of nuclease degradation. In sharp contrast, PEI-mediated transport of the same concentration of FAM-labeled 10 mer oligonucleotide into abalone sperm cells, resulted in almost 100% bright fluorescent nuclei (Fig. 1E). Using these sperm for fertilization, fluorescent microscopy revealed that the sperm with fluorescence attached to the membrane of the fertilized eggs (Fig. 1F), indicating that the sperm are still capable of insemination after PEI/DNA complex treatment.

DISCUSSION

In animals, microinjection was the earliest technique developed to introduce foreign DNA into fertilized eggs. However, it is a difficult and time-consuming technique that requires sophisticated skills. Because of the opaqueness, stickiness, and buoyancy of the embryos, the invisibility of the pronuclei, the toughness of the chorion, and the high mortality of injected eggs, this is not a suitable method for gene transfer in most shellfish species. Gene transfer into abalone fertilized eggs with microinjection technology is extremely difficult because the eggs are surrounded with a tough chorion membrane. If the chorion membrane is removed, the embryos become fragile and are easily destroyed by micromanipulation. The eggs are opaque and the pronucleus is invisible, which makes it almost impossible to inject the DNA solution into the male or female pronucleus of the fertilized eggs, which is generally required in gene transfer with microinjection. The yolk in the eggs easily flows out when the eggs are pierced with the glass micro-

pinhead (Fig. 1A), which could cause the high mortality of the injected eggs. These difficulties also limit the number of eggs that can be injected, even though millions of eggs can be produced by one single female abalone. In this research, the high mortality of the injected eggs and the lack of expression of GFP, indicate that microinjection is not suitable for transferring genes into abalone.

These problems are partially solved by the use of the electroporation method or the sperm electroporation method. High gene transfer efficiency was reported when a recombinant plasmid, containing a beta-galactosidase cassette, was introduced into fertilized eggs of the red abalone *Haliotis rufescens* by electroporation (Powers et al. 1995). The conventional sperm vector method is neither effective nor stable, but it is quite successful when combined with the electroporation method. Sperm electroporation is again a difficult-to-control, and skill-demanding method and its application to marine shellfish is limited because of the high electrical conductivity of seawater. To enhance the efficiency and overcome the difficulties in transgenic shellfish research, here we propose the polyethylenimine-mediated sperm-vector (PEI-SV) method. The results indicate that PEI can promote DNA transfer into abalone eggs, especially when combined with the sperm vector method. A significant proportion (13.9%) of the fertilized eggs developed normally into blastomeres and expressed green fluorescent protein at high level, 7.6% of them survived to the trochophore stage after gene transfer with the PEI-SV method.

PEI is an aqueous organic macromolecule with high cationic charge density potential, which can be complexed with DNA. PEI/DNA complexes can be used for *in vitro* and *in vivo* gene delivery approaches. The excess of positive surface charges enhances the association of the complex with the plasma membrane of cells and facilitates their uptake by endocytosis (Wagner et al. 1991). Accordingly, PEI is effective in gene delivery into a variety of cell types even without the addition of cell binding ligands or endosomolytic agents (Wightman et al. 1999, Zatloukal et al. 1999). The *in-vivo* gene transfer efficiency of these DNA/polycation complexes into tumors also has been assessed (Kircheis et al. 1999). PEI possesses DNA binding and condensing activity, together with a high pH buffering capacity, that is believed to protect DNA from nuclease degradation and to enhance its exit from the endosomal compartment (Bieber et al. 2002, Pollard et al. 1998). Every third

atom of the PEI is a protonable amino nitrogen atom, which makes the polymeric network an effective "proton sponge" at virtually any pH (Boussif et al. 1995). The intracellular transport pathway from the endosome to the nucleus is still not well understood. In this research, the higher gene transfer efficiency of the PEI-SV method, and the detection of reporter gene in the sperm cells, revealed that PEI is also effective in delivering genes into abalone sperm cells. The mechanism is presumably that the PEI/DNA complex is taken up by endocytosis and then carried into the eggs by the sperm cells. Whether DNA is integrated into the nucleus of the sperm cells before or after fertilization is under further investigation.

In the PEI group, the result showed that PEI decreased the survival rate and the gene delivering efficiency was low, which was presumably because the chorion of the abalone fertilized eggs blocked the PEI/DNA complex from entering. The mosaic expressions of GFP suggest that the PEI can deliver genes into one or more cells rather than into all cells of the embryos at two or more cell stages. The fertilization rate and survival rate of the PEI-SV group were significantly lower than the control group, which is presumably because of the lower motility of the sperms caused by the viscosity or cytotoxicity of the PEI. Recently, for its DNA-condensing and pH-buffering properties, PEI has been widely used as a highly efficient nonviral vector in gene therapy for delivering oligonucleotides and plasmids both *in vitro* and *in vivo* (Putnam et al. 2001, Kircheis et al. 1999). However, it was found that high concentrations of PEI/DNA complexes (>6 mg/mL) induced a cellular toxic response in cultured mammalian cells (Boussif et al. 1995). In this study, the lower fertility rate and survival rate of the PEI group and the PEI-SV group, compared with the control group, showed that PEI may be cytotoxic to the abalone sperm cells or embryo cells. Nevertheless, the PEI-mediated sperm-vector method is far more efficient and convenient compared with the conventional methods, and is potentially a powerful tool in transferring genes into other shellfish, fish, and even mammalian species.

ACKNOWLEDGMENT

IDENTIFICATION OF AN α -PEPTIDE IN *HALIOTIS RUBRA* WITH HOMOLGY TO THE *LYMNAEA* α -CDCP SPAWNING PEPTIDE

SCOTT F. CUMMINS AND PETER J. HANNA*

School of Biological and Chemical Sciences, Deakin University, Geelong, VIC 3217, Australia

ABSTRACT It is now understood that a combination of molluscan reproductive peptides are commonly cleaved from a large preprohormone and influence different aspects of spawning behavior. One type of reproductive peptide, known in *Lymnaea stagnalis* as α -CDCP, and in *Aplysia californica* as α -BCP, acts in egg laying via temperature-dependent autoinhibition or autoexcitation of neuronal cells. In our study, the expression of α -CDCP-like peptide in the blacklip abalone, *Haliotis rubra*, was identified by Western blots and immunocytochemistry, using an antiserum developed against α -CDCP. Western blots of total protein isolated from the central nervous system, cerebral and pleuropedal ganglia, as well as gonad and hepatopancreas tissues of sexually mature adults, identified a protein of approximately 100 kDa as well as a range of smaller reactive peptides. This finding suggests that a reproductive α -peptide is probably synthesized from a single larger precursor protein. The larger peptides were also identified in Western blots of several abalone tissues. Immunocytochemistry using the same antiserum showed the presence of immunoreactive axons in all the tissues studied, indicating synthesis or transport of products. The function of the abalone α -CDCP-like peptide is yet to be determined.

KEY WORDS: *Haliotis rubra*, egg-laying behavior, neuropeptides, α -CDCP

INTRODUCTION

Gastropods have been commonly used to study the neuronal basis of behavior due to the simplicity of their nervous systems. Examples include *Aplysia* and *Lymnaea*, in which reproduction is characterized by a stereotyped behavioral repertoire, controlled by several neuropeptides and culminates in egg laying (Nambu & Scheller 1986, Rothman et al. 1992, Griffond et al. 1992, Van Minnen et al. 1989).

Recombinant DNA technologies have been used to identify and characterize sequences encoding neuropeptides that are associated with the egg laying. These studies have indicated that, like most neuroactive peptides, biologic peptides are initially synthesized and cleaved from a large preprohormone sequence, known as the egg-laying hormone (ELH) preprohormone (Scheller et al. 1982, Scheller et al. 1983, Mahon et al. 1985, Nambu & Scheller 1986). The preprohormone characteristically begins with an initiator methionine residue, a hydrophobic signal sequence, and is followed by a number of cleavage sites (Shyamala et al. 1986). The ELH gene family is defined by the presence of a highly conserved ELH domain, and in *Aplysia* this corresponds to approximately 36 amino acids, while β -, α -, γ -, and callfluxin-related bag cell peptides (BCPs) may be present or absent. The *A. californica* gene family consists of five genes, three of which have been well defined, including a BC precursor isolated from BCs and peptides A and B precursors preferentially expressed in the atrial gland (Scheller et al. 1983). Immunolocalization studies have indicated that ELH expression is not restricted to the BCs and the atrial gland because the abdominal ganglion proper, the pleural, cerebral, and buccal ganglia have also been implicated as immunoreactive cell tissues (Shyamala et al. 1986).

It is now understood that, in *Aplysia*, a combination of peptides can be produced from a prohormone and each can influence a different aspect of behavior (Dudek & Tobe 1978, Shyamala et al. 1986, Geraerts et al. 1988). One important peptide derived from the precursor, α -BCP, is produced by the neurosecretory BCs upon

excitation, and acts via a temperature-dependent autoinhibition or autoexcitation of the BCs (Rothman et al. 1983, Sigvardt et al. 1986, Redman & Berry 1991). Following release it is rapidly inactivated (Sigvardt et al. 1986). The α -BCPs are 100% identical in primary sequence across all Aplysiidae species so far examined (Li et al. 1999). The amino acid sequence is Ala-Pro-Arg-Leu-Arg-Phe-Tyr-Ser-Leu.

In *Lymnaea*, egg laying is also triggered by an array of neuropeptides, encoded by an ovulation hormone gene family, including the caudodorsal cell hormone (CDCH) I and II gene precursors (Vreugdenhil et al. 1988). These precursors produce at least nine caudo-dorsal cell peptides (CDCPs), including a 9 amino acid sequence encoding α -CDCP. Despite belonging to a different gastropod class to *Aplysia*, the α -CDCP retains the residues Arg-Leu-Arg-Phe, as encoded by the α -BCP gene. The CDCH precursor has a calculated molecular weight of 25 kDa, but due to a high percentage of charged amino acids, it migrates at 35 kDa in pulse-label experiments (Geraerts et al. 1985).

The first report of neuropeptide involvement in abalone reproduction was by Yahata (1973), who observed induced spawning of abalone after injection of homogenized ppg and visceral ganglia of mature females. Injections of homogenized cerebral ganglia (cg) produced no notable change in the ovaries. More recently, neurosecretion in the cg, ppg, and visceral ganglia was investigated in *H. discus hannai*, to determine the role of hormones in the regulation of reproduction (Hahn 1994). He found two types of cells in the cg that appeared to be neurosecretory. In another study involving the cg of *H. asinina*, two types of neurosecretory cells (NS), NS₁ and NS₂, were identified (Upatham et al. 1998). However, there is no experimental proof that the peptides produced in these cells regulate reproduction and growth.

A nucleotide sequence containing an abalone ELH (aELH) has been cloned from *H. rubra*, and shows high homology with the sequences of the CDCH of *Lymnaea* and ELH of *Aplysia* (Wang & Hanna 1998). However, no sequences have been obtained that encode an abalone α -CDCP-like peptide. Therefore, the current research work aimed to characterize α -CDCP-like immunoreactive structures within the abalone neural and reproductive systems to determine whether a homologous peptide was present.

MATERIALS AND METHODS

Animals and Tissue Preparation

Mature male and female *H. rubra* (Leach) with ripe gonads were collected from Port Phillip Bay (Victoria) under Fisheries research permits (97/R/049A and RP 626). Tissues were then dissected for analyses of proteins, as well as preparation of tissue sections.

For protein extraction, approximately 200 mg of tissue was macerated, suspended in 2 mL SDS lysis buffer (2% SDS, 50 mM Tris-HCl (pH 7.2), 1 mM β -mercaptoethanol) and boiled for 3 min. The sample was homogenized (Industrial Equipment) and then boiled for a further 5 min. Protein solutions were microcentrifuged (Microcentaur MSE) at 13,000 rpm for 10 min and supernatant collected for storage at -70°C . Protein concentration was quantified using the Bradford method for protein quantitation (Kruger 1996).

Paraffin sections were prepared for immunocytochemistry by firstly fixing dissected tissues in freshly prepared 4% paraformaldehyde in 0.1 M phosphate buffer (pH 7.4) at 4°C for 24 h. They were then transferred to phosphate buffer and stored at 4°C before dehydration in an ascending ethyl alcohol series, xylene, then embedding in paraffin. Serial sections of 8 μm were cut with a microtome (Triangle Biomedical, CUT Series Rotary Microtome) and mounted on gelatin-coated slides. Paraffin sections of *H. discus hannai* ppg were kindly provided Dr. Kirk Hahn.

Antibodies Against L. stagnalis α -CDCP

Antiserum against α -CDCP peptide was kindly provided by Dr. Gregg Nagle (University of Texas Medical Branch, Galveston, Texas). This polyclonal antibody was made in rabbit and recognizes residues 144–152 (Glu-Pro-Arg-Leu-Arg-Phe-His-Asp-Val) of the *L. stagnalis* CDCH precursor (Vreugdenhil et al. 1988).

Western Blots

Larger proteins and peptides were separated by 12% SDS-PAGE using the method of Laemmli (1970), then electro-transferred by a Mini-Blot apparatus (Bio-Rad) to 45- μm nitrocellulose sheets (Bio-Rad). After transfer, the membrane was incubated with 5% bovine serum albumin (BSA) in phosphate-buffered saline (PBS; 50 mM NaH_2PO_4 and Na_2HPO_4 , 154 mM NaCl, pH 7.4) for 2 h at room temperature (RT), with agitation. The membranes were incubated with the primary antibody, rabbit anti- α -CDCP, at a dilution of 1:1,000 (in Tris-buffered saline [TBS; 20 mM Tris-HCl pH 7.5, 500 mM NaCl] with 3% BSA) for 2 h. After several washes with PBS, the binding was visualized using HRP-coupled goat antirabbit antibody (Sigma), followed by enhanced chemiluminescence (Amersham) according to the manufacturer's instructions.

Identification of small immunoreactive peptides was performed after 12% SDS PAGE (Gradipore) in Tris-Tricine buffer and subsequent electro-transfer to polyvinylidene fluoride (PVDF) sheets (Bio-Rad). Detection of α -CDCP-like peptides was performed as for the larger peptides.

Immunocytochemistry

Immunofluorescence was performed following dewaxing and rehydration of tissue sections. Blocking was then carried out, first in 1% glycine for 30 min, then in 4% BSA for 30 min. Sections were incubated for 1 h at RT in primary antibody (anti- α -CDCP) diluted 1:500 in PBS, rinsed three times in PBS, then incubated for

1 h at RT with FITC-labeled goat antirabbit secondary antibody (Sigma). Sections were rinsed three more times in PBS, and then mounted in FITC mounting solution (90% glycerol, 4% n-propyl-gallate in 50 mM PBS pH 8.2). The preparations were examined under a fluorescence microscope (Leica) and the images were captured with a Spot cooled CCD camera (Diagnostic Instruments).

Immunoenzyme staining was performed following dewaxing and rehydration of tissue sections. Endogenous peroxidase activity was quenched by incubation of sections in 3% H_2O_2 in methanol for 10 min. After washing in PBS, blocking was performed, first in 1% gelatin for 30 min then in 4% BSA for 30 min. Sections were rinsed three times in PBS, incubated for 1 h at RT in primary antibody diluted 1:1000 in PBS, then rinsed three times in PBS, and incubated in HRP-labeled goat antirabbit secondary antibody (Sigma) in the dark at RT. After three rinses in PBS, the sections were developed in 3-amino-9-ethylcarbazole (AEC) substrate solution (ICN). When sufficient color occurred, development was stopped by a wash in distilled water, and the sections counterstained in Mayer's haematoxylin. After a further wash the sections were mounted in Faramount aqueous mounting solution (DAKO) and viewed under a Zeiss Axioskop MC 80 microscope. Images were captured on a Spot cooled CCD camera (Diagnostic Instruments).

Controls

For each experiment it was important to perform controls to ensure antibody specificity. Immunoreactivity of the respective peptides was not observed following antibody preincubation with crude abalone tissue protein (data not shown). Also, no immunoreactivity was observed when blots or sections were incubated with no primary antibody (data not shown).

RESULTS

Immunoblotting

Figure 1A shows the results of Western blots of combined cg and ppg tissues, mature male gonad (mgo), and mature female gonad (fgo) sample separations transferred to nitrocellulose and reacted with anti- α -CDCP as the primary antibody. In the combined cg-ppg sample, a protein was identified of approximately 100 kDa. The mature mgo and fgo also contained the 100 kDa protein, but also contained immunoreactive proteins approximately 48 kDa and 46 kDa in size.

Additional smaller immunoreactive proteins were identified by chemiluminescence detection in Western blots performed using SDS-PAGE in Tris-Tricine buffer and transfer to PVDF membranes (Fig. 1B). The combined cg-ppg sample now showed the presence of the 48 kDa and 46 kDa proteins, as well as additional smaller ones of approximately 36 kDa and 29 kDa. The mgo contained additional immunoreactive 32 kDa and 22 kDa proteins, whereas the fgo contained additional 36 kDa, 28 kDa, and 23 kDa proteins.

Western blots of fractionated total proteins isolated from the *H. rubra* heart, foot, rectum, gill, and tentacle also showed a 100 kDa protein that was immunoreactive with anti- α -CDCP (Fig. 1C). As well, the 48 and 46 kDa proteins were also present in all tissues, except the foot tissue.

Immunocytochemistry

Immunocytochemistry studies, using an anti- α -CDCP probe on sections of neural and gonadal tissues, showed strong positive

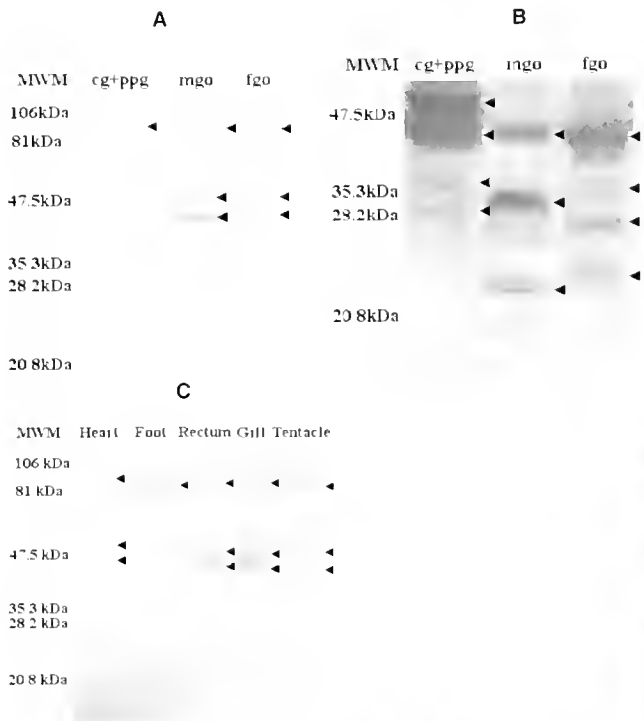

Figure 1. Western blots of *H. rubra* tissues using an anti- α -CDCP. Total proteins were isolated from *H. rubra* tissues then separated by 12% SDS-PAGE with Tris-Glycine buffer or 12% SDS-PAGE with Tris-Tricine buffer, and electro-transferred to nitrocellulose or PVDF, respectively. After blocking, the membranes were then reacted with rabbit anti- α -CDCP, followed by HRP-conjugated antirabbit Ig, and detection was achieved using ECL reagents (Amersham). Arrows show localization of immunoreactive proteins. MWM, prestained molecular weight markers (Bio-Rad). **A.** Immunodetection of 100 kDa in the combined cg and ppg tissues, and 100, 48, and 46 kDa proteins in the mgo and fgo (SDS-PAGE then nitrocellulose). **B.** Immunodetection by chemiluminescence showing additional 48, 46, 36, and 29 kDa proteins in the combined cg and ppg tissues, 32 and 22 kDa proteins in the mgo, and 36, 28, and 23 kDa proteins in the fgo (SDS-PAGE then PVDF). **C.** Immunodetection of a 100 kDa protein in total protein extracts of heart, foot muscle, rectum, gill, and tentacle, as well as 48 and 46 kDa proteins in all tissues, except the foot muscle (SDS-PAGE-nitrocellulose).

results (Figs. 2A to H). The cg and ppg of the mature *H. rubra* contained numerous immunopositive cells (Figs. 2A to F). Immunoreactive cells of the cg were distributed throughout the cortex, but were mainly located within the outer cells and within the inner cortex (Figs. 2A and B). The outer cells appear to be the neurosecretory NS₁ and NS₂ cells identified by Upatham and colleagues (1998). A large number of immunoreactive axons were found to extend into the medulla of the left and right cg, and through the dorsal cerebral commissure.

The ppg also contained abundant immunopositive cells that were distributed within the cortex region (Figs. 2C and D). Many of these cells were likely to be of the NS type because they were located close to the basement membrane. In addition, the immunoreactivity was strong, indicating there was a large amount of reactive protein present. A high density of immunoreactive axons was identified transversing the medial and lateral regions of the medulla in the ganglion mass, and extending into the pedal and cerebropleural connectives (Figs. 2E and F). No immunoreactiv-

ity was observed within the statoysts. As well, no difference was observed in peptide distribution in the neural tissues between female or male *H. rubra*.

To show conservation between abalone species, ppg sections prepared from *H. discus hannai* were also tested with anti- α -CDCP. Numerous immunopositive fibers were present in the medulla of the ppg of *H. discus hannai* (Fig. 2G). No reactivity was seen in the cortex, possibly due to Stieve's fixative used to prepare these ganglia, and the antibodies may not have been able to penetrate cortex cells, the antigen destroyed by fixation, or the peptide was not present in these cells. However, as observed in *H. rubra*,

Figure 2. Immunocytochemical localization of an α -CDCP-like peptide in *H. rubra* and *H. discus hannai* neural tissues. Sections were first incubated with rabbit anti- α -CDCP, prior to detection with HRP-conjugated antirabbit Ig and an AEC substrate to produce a red color, or immunofluorescence using FITC-conjugated antirabbit Ig. Sections were counterstained with hematoxylin. **A** and **B.** *H. rubra* sections showing immunoreactivity in the cortex cells (arrows) of a cg and axons (arrowhead) extending into the medulla (bars 18.75 and 25 μ m, respectively). **C.** *H. rubra* section showing immunoreactivity in cortex cells (arrows) of a ppg (bar 25 μ m). Inset is a high power micrograph showing abundant staining (arrowhead) of a cell at the basement membrane. **D** and **E.** Immunofluorescence in *H. rubra* axons located in the medulla of a ppg (bars 25 μ m). **F.** Immunopositive reactivity in axons that extend laterally into the pedal ganglia from the ppg (bar 25 μ m). **G** and **H.** *H. discus hannai* immunopositive axons (arrows) in the medulla of a ppg. Asterisk indicates the area of an immunoreactive loop (bars 50 μ m and 25 μ m, respectively).

intensely stained axons were observed throughout the medulla, and appeared to form a loop (Fig. 2H).

Immunoreactive material to anti- α -CDCP was localized in the fgo and mgo of *H. rubra* (Fig. 3A to C). In the fgo, immunopositive protein was demonstrated in special cells and fibers of the trabeculae (Fig. 3A). In addition, a small number of immunoreactive cells and fibers were identified within the gonad capsule, and the hepatopancreas capsule (Fig. 3B), but never within the oocyte nucleus. Control sections corresponding to the same tissue resulted in no positive signals. The level of immunoreactivity in the gonads appeared to differ between individual animals, possibly as a result

of oocyte maturation. In the mgo, immunoreactivity was restricted to cells and fibers of the trabeculae (Fig. 3C), as observed in fgo. Also, a small number of immunoreactive cells were located within the gonad capsule and hepatopancreas capsule (data not shown).

DISCUSSION

The focus of our research involves the eg, ppg, and gonad tissues, due to their importance in gastropod reproduction (Geraerts et al. 1988, Yahata 1973). The difficulty associated with the isolation of the visceral ganglia hindered any experimental analysis on this tissue.

The expression of an α -CDCP-like peptide in abalone was firstly identified by Western blots. Total protein isolated from abalone tissues confirmed that the anti- α -CDCP probe was reactive to a protein of 100 kDa in the combined eg and ppg tissues, as well as the gonads of *H. rubra*. Reactive peptides of 46 and 48 kDa were also detected in the gonad tissue. This finding was consistent with peptides being synthesized from a 100-kDa precursor protein, but was larger than the 32 kDa identified in *Aplysia* (Berry 1981), or 25 kDa as observed in *Lymnaea* (Geraerts et al. 1985).

Due to the small size of a fully processed α -CDCP (9 aminoacids), it was expected that a homologous α -CDCP-like peptide in abalone would not be detected in standard blots. However, a number of possible intermediates were observed and is consistent with the findings in *A. californica*, that post-translational processing by specific convertases produces peptides of different sizes and these can be post-translationally modified (Fisher et al. 1988). They showed by Western blot analysis that antibodies recognized small final-product peptides and intermediates in the processing pathway, but all contained the sequence encoding the immunogen. Thus, the different sized bands observed in *H. rubra* Western blots probably represent differential cell processing of the polypeptides. Our results indicate that the abalone precursor of 100 kDa is initially processed to release a 35-kDa protein (α ELH immunoreactive, Cummins et al. 2002) and a 48-kDa protein (α -CDCP immunoreactive, this study), prior to further processing. If this is correct, the size of the precursor is much larger than that shown for the *Aplysia* ELH egg-laying precursor peptide (32 kDa), and may indicate that the genetic make-up of the *H. rubra* reproductive precursor is different to *Aplysia* and *Lymnaea* homologues. However, the multiple bands may also be the result of expression of a multigene α ELH family, as shown in *Aplysia* species (Scheller et al. 1983), in which different expression occurs in different tissues.

Western blots also showed the α -CDCP-like peptide distribution in the heart, foot muscle, rectum, gill, and tentacle tissue, suggesting that these peptides may have a broad function in this animal. Similarly, peripheral tissues in *L. stagnalis* are known to contain immunoreactive material to egg-laying peptides (Van Minnen et al. 1989). However, subsequent immunohistochemical analyses in this laboratory have shown that immunoreactivity is predominantly localized to neural ganglia, therefore the other positive material may only be an indication of transport of protein or peptides.

Previous immunocytochemical studies have successfully used antibodies against *Aplysia* and *Lymnaea* egg-laying peptides to demonstrate their presence in the neural systems of other invertebrates. For example, peptides homologous to ELH have been immunolocalized in the neural cells of *Busycon* and *Mytilus* (Ram et al. 1998, Croll et al. 1993). Also, α -CDCP is expressed in the

Figure 3. Immunocytochemical localization (arrows) of an α -CDCP-like peptide in *H. rubra* gonad and hepatopancreas tissues. Sections were treated as in Fig. 2. A. Immunoreactivity in cells of the fgo trabeculae (bar 25 μ m). B. Immunoreactivity in cells of the hepatopancreas capsule of a fgo (bar 27.5 μ m). C. Immunoreactivity in cells of the mgo trabeculae (bar 25 μ m).

neural network of *Helix aspersa*, *Mytilus edulis*, and *Busycon canaliculatum* (Croll et al. 1993, Ram et al. 1998). In a previous study, peptides immunoreactive to antisera against CDCH, α -CDCH and β -CDCH, showed positive immunoreactions in tissues of *Sarcophaga bullata* (Diptera), *Leptinotarsa decemlineata* (Coleoptera), *Loensta migratoria*, and *Periplaneta americana* (Orthoptera) (Theunis et al. 1990). More recently, it has been shown that antisera directed against the same three peptides results have been detected in the central nervous system of the rhyonobdellid leech, *Theromyzon tessulatum* (Salzet et al. 1997).

Our use of anti- α -CDCP in immunocytochemistry has demonstrated that an α -CDCP-like peptide is extensively distributed throughout *H. rubra* cg and ppg tissues. These results imply that the cg could be important in the regulation of reproduction in gastropods. The same distribution pattern was observed for aELH (Cummins et al. 2002), and enhances the possibility that these peptides are translated as a single precursor. Immunoreactivity appeared to be localized to the NS₁ or NS₂-type cells in the cortex. However, it seemed that the distribution of immunoreactive cells containing aELH and α -CDCP-like peptide were not concentrated within one specific region or cluster of cells, but they were widely distributed within the cortex cells and axons. These reproductive peptides may be released from much of the surface of the nervous system and not just from well-defined neurohemal organs. This is unlike studies of other molluscs, in which antisera have been shown to react with specific clusters of neuronal populations in the ganglia (i.e., such as the immunoreactivity pattern of antiCDCH in *L. stagnalis* (Van Minnen et al. 1988). However, we did observe axonal loops within the medulla of ganglia by anti- α -CDCP immunolocalization. It has been suggested that similar loops in *L. stagnalis* are important sites of synaptic integration (Van Minnen et al. 1988).

Concerning the function of the immunoreactive neurons, it is possible that reproductive peptide colocalization may facilitate their simultaneous release into the surrounding hemolymph, as is the case in other gastropods (Chiu & Strumwasser 1981, Bernheim & Mayeri 1995). Extensive immunoreactive axonal distribution throughout the medulla of the cg and ppg suggests that these may lead to sites of neuropeptide release. In *Lymnaea*, the CDCs release egg-laying peptides into the hemolymph via neurohemal areas and also from blind ending axons in the medulla of the commissure (Van Minnen et al. 1989). We can also speculate that, similar to *Aplysia* and *Lymnaea*, *H. rubra* reproductive peptides too may control reproduction through autoexcitation or autoinhi-

bition of other neural tissues. However, to fully elucidate their biologic activity, further experiments involving the identification of a precursor sequence, bioassays and electrophysiology would be required. Given that abalone are broadcast spawners (not internal fertilizers), peptide function will invariably be different to *Aplysia* and *Lymnaea*. Further investigations are also required to provide a more detailed analysis of the cellular structure of the immunoreactive cells. Although our study using light microscopy predicts that they are of NS type, more definitive ultrastructural studies would provide more precise details.

Despite extensive research being conducted on neuropeptide immunoreactivity within the central nervous system, relatively little research has focused on the reproductive tissue. However, CDCH genes have been immunocytochemically localized to the female part of the reproductive tract and exocrine secretory cells of the male part (Van Minnen & Vreugdenhil 1987). Our study has shown that an α -CDCP-like peptide is present in the trabeculae of the fgo and in mgo trabeculae of *H. rubra*. The peptide was only located within certain cell types, which may function as a peptide storage cell for the maturing gonad. It has been suggested that the granulated cells of the gonad trabeculae are the endocrine cells of the gonads (Apisawetakan et al. 2001). Indeed, recent immunocytochemical experiments performed using anti-aELH on *H. asinina* gonad tissues, have shown high immunoreactivity in the granulated cells (Chanpoo et al. 2001). The large amount of reproductive-like peptides within the fgo may be a function of the gastropod requirement to release high concentrations of hormone into the hemolymph or gonad to cause maturation of oocytes prior to spawning. It is known in molluscs, that hormone release areas are high in number (Joosse 1988).

The observation of reproductive peptides in the male *H. rubra* trabeculae is not unusual. Evidence from *Drosophila melanogaster* shows that when a male mates and releases sperm, he also deposits an ELH that induces egg laying in the female (Park & Wolfner 1995). This hormone is related, by use of cross-reactive antisera, to the ones found in gastropods and other invertebrates. In addition, *L. stagnalis* CDCH gene products are known to be secreted into the male duet and transferred to the female copulant during copulation, and may function to accelerate the start of egg laying (Van Minnen et al. 1989). Thus, *H. rubra* trabeculae reproductive peptides may play a similar role, but because they are spawners, this role may be altered.

In summary, these results indicate that α -CDCP-like peptide could play a significant role in abalone reproduction.

GENETIC STRUCTURE OF CULTURED *HALIOTIS DIVERSICOLOR SUPERTEXTA* (REEVE) POPULATIONS

ZHONGBAO LI^{1,2*} AND CHANGSHENG CHEN¹

¹Fisheries College, Jimei University, Xiamen, Fujian 361021, People's Republic of China; ²School of Marine and Environmental Studies, Xiamen University, Xiamen, Fujian 361005, People's Republic of China

ABSTRACT Genetic structure of four cultured *Haliotis diversicolor supertexta* populations were investigated using the assay of vertical slab polyacrylamide gel electrophoresis. Low levels of genetic diversity of populations was found: mean numbers of alleles per locus ranged from 1.4 to 1.5; proportions of polymorphic loci ($P_{0.99}^c$) ranged from 27.78 to 33.33; observed heterozygosities ranged from 0.120 to 0.150; expected heterozygosities ranged from 0.123 to 0.131. The results showed that the coefficient of gene differentiation among populations was low ($F_{ST} = 0.04$), gene flow among populations was large ($Nm = 6$). Genetic structure was very similar among four cultured populations. The genetic distances between any two of the four populations were 0.002–0.009, with an average of 0.0047.

KEY WORDS: *Haliotis diversicolor supertexta*, allozyme, genetic structure, genetic diversity, genetic differentiation

INTRODUCTION

Haliotis diversicolor supertexta (Reeve) is widely distributed in China and Japan (Nie & Wang 2000). In recent years, *H. diversicolor supertexta* has been playing an economically important role in the fishing and farming industries of China. Numerous studies on the culture and ecology have been undertaken on *H. diversicolor supertexta*, however, few are concerned with genetic structure. Knowledge of genetic structure among populations is particularly important for managing exploited species. This knowledge is used in aquaculture to assess the potential for adaptive divergence available from different sources of broodstock. To protect this valuable marine resource and supply genetic information for the study of genetics and breeding, it is necessary to investigate and assess the genetic structure of *H. diversicolor supertexta* population.

Allozyme electrophoresis is considered to be an extremely useful technique in population genetics (Allendorf & Utter 1979, Lavery & Shaklee 1991). Within the genus *Haliotis* this kind of study has only been carried out in *H. fulgens* (Zúñiga et al. 2000), *H. roei* Grey (Hancock 2000), *H. rubra* Leach (Brown 1991, Brown & Murray 1992) and *H. laevigata* Donovan (Brown & Murray 1992). This technique is used in the present study to examine the genetic structure of cultured *H. diversicolor supertexta* populations. In this study we describe the pattern of population genetic structure in four cultured *H. diversicolor supertexta* populations from one commercial abalone farm of Dongshan (population 1) and three commercial abalone farms of Zhangpu (population 2, population 3, and population 4) in Fujian Province, using allozyme analysis. The results can be useful for protecting and improving the resources of this species.

MATERIALS AND METHODS

Samples

Vertical slab polyacrylamide gel electrophoresis was used to estimate genetic structures and genetic diversities of the four cultured *H. diversicolor supertexta* populations. One hundred and twenty eight individuals were collected in 2002 from one commercial abalone farm in Dongshan (population 1, 32 individuals)

and three commercial abalone farms in Zhangpu (population 2, 32 individuals; population 3, 32 individuals; and population 4, 32 individuals) in Fujian Province. They were alive on the way to the laboratory. A muscle tissues was dissected from each individual and preserved in a deep freezer at -80°C . The muscle sample (0.5 g) was homogenized with Tris-HCl extract solution (pH = 7.0). The homogenates were centrifuged at 12000 rpm for 15 min at 4°C . The supernatant was then collected for electrophoresis.

Electrophoresis

The allozymes were detected using polyacrylamide gel electrophoresis (PAGE). The buffer systems and staining procedure followed those described by Taniguchi and Sugama (1990), Zen and Xiang (1989), and Wang (1996). A total of 10 enzymes at 18 loci were analyzed: lactate dehydrogenase (LDH, E.C.1.1.1.27), superoxide dismutase (SOD, E.C.1.15.1.1), esterase (EST, E.C.3.1.1-), aspartate aminotransferase (AAT, E.C.2.6.1.1), alcohol dehydrogenase (ADH, E.C.1.1.1.1), malic enzyme (M E, E.C.1.1.1.40), malate dehydrogenase (MDH, E.C.1.1.1.37), sorbitol dehydrogenase (SDH, E.C.1.1.1.14), isocitrate dehydrogenase (IDH, E.C.1.1.1.42), and amylase (AMY,3.2.1.1). The names, abbreviations and numbers of the enzymes were described by Shaklee et al. (1990), and the description of the loci and alleles by Wang (1996).

Statistical Analysis

To assess the genetic diversities of the four populations, the allele frequencies, the mean numbers of alleles per locus (A), the proportions of polymorphic loci (P), observed heterozygosities (H_o), and expected heterozygosities (H_e) at Hardy-Weinberg equilibrium were calculated (Wang 1996). A locus was considered to be polymorphic ($P_{0.99}^c$) if the frequency of most common allele was equal or less than 0.99 at one or more localities. To estimate the degree of genetic differentiation among populations, the genetic distances between any two of the four populations were calculated using Nei's formulas (Nei 1978), the coefficient of gene differentiation (F_{ST}) among populations was calculated following Wright (1977), and gene flow among populations (Nm) was calculated using Wright's formulas (Wright 1969). Dendrogram from the matrix of genetic distances was constructed using unweighted pair group method with arithmetic averaging (UPGMA, Sneath & Sokal 1973). Data were analyzed using BIOSYS-1 software (Swofford & Selander 1989).

	B	0.563	0.313	0.438	0.583

RESULTS

Ten enzymes coded by 18 loci were clearly resolved in all populations (Li et al. 2004a). Six loci (*Est-2*, *Est-3*, *Mdh-1*, *Sdh-2*, *Aat-1*, *Amy-1*) were polymorphic in at least one population among populations. Allele frequencies at polymorphic loci in four cultured *H. diversicolor supertexta* populations are presented in Table 1 and showed little variability among them.

Low levels of genetic diversity were estimated in the four cultured *H. diversicolor supertexta* populations (Table 2). The mean numbers of alleles per locus ranged from 1.4 to 1.5. The proportions of polymorphic loci ($P_{pol\%}$) ranged from 27.78 to 33.33. Observed heterozygosities ranged from 0.120 to 0.150. Expected heterozygosities ranged from 0.123 to 0.131. The genetic diversity was very similar among populations.

To estimate the degree of genetic difference among the four populations, the coefficient of gene differentiation (F_{ST}) and the genetic distance (D) were calculated. The coefficient of gene differentiation among populations was 0.04 (Table 3). The genetic distances between any two of the four populations were 0.002–0.009, with the average of 0.0047, the genetic identities between any two of the four populations were 0.991–0.998, with the average of 0.9953 (Table 4). Gene flow was large ($Nm = 6$) (Table 3). The UPGMA dendrogram of four cultured *H. diversicolor supertexta* populations was shown in Figure 1. The first formed by population 1 and population 2 at a distance of 0.002. The second

formed by population 3 and population 4 ($D = 0.002$), which was linked to the first cluster at a distance of 0.006.

DISCUSSION

Genetic diversity is fundamental for the maintenance of species, population, and ecosystem diversities. Many studies have demonstrated that a loss of genetic diversity leads to a reduction in the adaptive fitness of a population, increasing the risk of extinction (Vrijenhoek 1994). In the present study, low level of genetic diversity was estimated in the four cultured *H. diversicolor supertexta* populations (Table 2). The proportions of polymorphic loci of *H. diversicolor supertexta* populations ranged from 27.78 to 33.33, which was lower than that of 48 kinds of seashells ($P = 0.471 \pm 0.159$) (Singh 1984). The proportion of polymorphic loci is influenced by the number of loci examined. The average observed heterozygosity we found among *H. diversicolor supertexta* populations ($H_o = 0.135$) was similar to those reported for *H. rubra* ($H_o = 0.136$; Brown 1991), *H. fulgens* ($H_o = 0.119$; Zúñiga et al. 2000), *H. discus hannai* Ito ($H_o = 0.123$; Fujio et al. 1983) and 48 kinds of seashells ($H_o = 0.147$; Singh & Green 1984), however, lower than that of *H. laevigata* ($H_o = 0.195$; Brown & Murray 1992) and higher than that of 10 kinds of invertebrates ($H_o = 0.098$; Powell 1975). It is probably a reasonable assumption that the amount of isozyme variation reflects the relative amount of genetic variation found at other loci in the genome (McAndrew & Majumder 1983). Six loci (*Est-2*, *Est-3*, *Mdh-1*, *Sdh-2*, *Aat-1* and *Amy-1*) in 18 gene loci were polymorphic in at least one population among populations. From the genetic point of view, *Est-2*, *Est-3*, *Mdh-1*, *Sdh-2*, *Aat-1* and *Amy-1* can be used as the biochemical genetic markers of *H. diversicolor supertexta* for genetic diversity assessment and selective breeding program. Similar studies have been carried out in *H. diversicolor diversicolor* (Li et al. 2004a), *H. discus discus*, and *H. discus hannai* (Li et al. 2004b).

TABLE 4.
Genetic distances (above diagonal) and genetic identities (below diagonal) among cultured *Haliotis diversicolor supertexta* populations.

Population	1	2	3	4
1	****	0.002	0.009	0.004
2	0.998	****	0.006	0.005
3	0.991	0.994	****	0.002
4	0.996	0.995	0.998	****

Figure 1. The unweighted pair group method with arithmetic averaging (UPGMA) of the four cultured *Haliotis Diversicolor supertexta* populations.

Genetic structure was very similar among four cultured populations. The coefficient of gene differentiation among populations was low ($F_{ST} = 0.04$), with 4% gene differentiation of the total diversity coming from interpopulation and 96% from intrapopulation. The result showed that gene flow among populations in our study was large ($Nm = 6$) (Table 3). The estimate obtained in this study for F_{ST} values in *H. diversicolor supertexta* is in general agreement with those reported for *H. cracherodii* ($F_{ST} = 0.039$; Hamm & Burton 2000), *H. fulgens* ($F_{ST} = 0.036$; Zúñiga et al.

2000), *H. rubra* ($F_{ST} = 0.022$; Brown 1991), *H. laevigata* ($F_{ST} = 0.014$; Brown & Murray 1992), *H. rufescens* ($F_{ST} = 0.012$; Burton & Tegner 2000) and *H. roei* ($F_{ST} = 0.009$; Hancock 2000) within the genus *Haliotis*.

The mean genetic distance and mean genetic identity among populations were 0.0047 and 0.9953 respectively, which means that there were no significant differences in the biochemical genetic character among populations. Nei (1987) considers the threshold genetic distance between populations, between subspecies, and between species at about 0.01, 0.1, and 1.0. They belong to population level of *H. diversicolor supertexta*.

Modern fisheries science demands a holistic management of fisheries; this concept includes the maintenance of genetic diversity and population structure, which are critical for ensuring the long-term survival of any fishery (Shepherd & Brown 1993). The results in this study are likely to be indicative of population genetics of cultured *H. diversicolor supertexta* in China and the factors influencing it, which should be considered in the development of *H. diversicolor supertexta* conservation and future management plans.

RAPD ANALYSIS OF GENETIC DIVERSITIES OF THREE SPECIES OF ABALONE

TAIWU LI,¹ WENXIN YANG,² XIURONG SU,¹ ZHIBIAO YANG,¹ AND HAO GUO³

¹Faculty of Life Science and Biotechnology, Ningbo University, Ningbo, 315211, China; ²Life Science College, Liaoning Normal University, Dalian, 116029, China; ³National Marine Environment Monitoring Center, Dalian, 116023, China

ABSTRACT RAPD (random amplified polymorphic DNA) technique was applied to detect the genetic diversity in 3 species of abalone (*Haliotis discus hannai* Ino, *Haliotis discus discus* Reeve and *Haliotis diversicolor* Reeve). Twenty random primers, screened out of 100, gave 213 clear and informative fragments, ranging from 250–2600 bp, under predetermined optimal reaction conditions. There existed genetic diversity not only between species but also among individuals. The percentage of polymorphic loci, genetic heterozygosity, genetic identity, and genetic distance were calculated to reveal the diversities among species by using the Popgene32 software and a phylogenetic tree was constructed with the method of UPGMA. The results indicated that genetic variation in the population of *H. discus discus* is relatively high. *H. discus hannai* and *H. discus discus* showed a very close relationship with each other but a relatively distant relationship with *H. diversicolor*.

KEY WORDS: abalone, RAPD, genetic diversity

INTRODUCTION

RAPD marker can detect the insertion, loss of the binding sites distributed throughout the target genome with the differences of the amplified fragments. Compared with other molecular markers, such as RFLP, RAPD marker is simpler, lower time- and money-consuming and requires less DNA template, and doesn't need prior knowledge of DNA sequence. It has been widely used in genetic variability analysis, identification of relationship and genetic breeding and so on (Liu & Xiang 1996, Liu et al. 1996, Li & Zou 1999, Zhang et al. 2000) since it was established in 1990 (Williams et al. 1990, Welsh & McClelland 1990). In recent years, there were some successful reports in China and elsewhere, such as American system project of HHS (high health shrimp), oyster (Liu & Dai 1998), and shrimp (Song et al. 1998, 1999).

Abalone belongs to Mollusca, Gastropoda, Prosobranchia, Haliotidae, *Haliotis*. It is a precious marine shellfish with great value both as a health food and medicine, living on rocks and reefs at about 10 m depth from the low water mark. It is reported that there are seven species of abalone in China. Two of them have high economic value, namely *Haliotis discus hannai* Ino and *Haliotis diversicolor* Reeve. The former lives in the northern sea of China, Japan and Korea (Hou 1998), with that from Japan being regarded as a geographical subspecies of *Haliotis discus hannai*, named *Haliotis discus discus*. The latter is a warm sea species distributed in Fujian, Taiwan, Guangdong of China, and the south part of Japan. Previous studies mostly focused on ultrastructure (Liu et al. 2000, Ke et al. 2003, Cui et al. 2004) and diseases diagnosis (Li et al. 1998, Chen et al. 2000), but there are few systematic studies on the genetic diversity of abalone in China. In the present study, the RAPD technique was applied to assess the genetic diversity and the relative relationship of the three species of abalone to provide some potential theoretical reference for ecological protection and reasonable exploration of the marine resources.

MATERIALS AND METHODS

Samples

Twelve *Haliotis discus hannai* Ino were collected from Zhangzi Island of Dalian, Liaoning Province (named population Z), and nine cultured *Haliotis discus discus* provided by the Key Laboratory of Marine Bioengineering in Ningbo University, Zhejiang Province (population B), and 20 cultured *Haliotis diversicolor* Reeve from Xiamen, Fujian province sea area (population F).

Random Primers

Ten-Mer random primers were bought from Shengggong Biotechnology Ltd. Shanghai Co., 20 primers were screened from 100, using 1 animal from each group (Table 1).

Instruments & Reagents

Amplifications were carried out on the Gene Amp PCR system made by PERKIN ELMER Analyze Co. in US. Cary 100 Cone U-visible Spectrophotometer was used to test the purity and concentration of DNA. FR-980 biologic electrophoresis test system was used to take photographs of gels.

Proteinase-k, Taq DNA polymerase, and dNTP were the products of TaKaRa Co. The other A.R grade reagents were bought from local Chemical Reagents Co.

DNA Extraction

One hundred milligrams of abdominal foot muscle fixed with alcohol was incubated at 55 °C for about 4 h in microcentrifuge tubes containing TEN (10 mM Tris-HCl, Na₂-EDTA, 0.15 M NaCl, pH 8.3), 2% SDS and 200 µg Proteinase-K, then extracted with phenol/Chloroform (1:1), and then Chloroform: isopentanol (24:1). The supernatant fractions were mixed with two volumes of cold 100% alcohol and 1/10 volume of 3 M sodium acetate. The DNA quality was tested by running the samples in 0.7% agarose gel containing ethidium bromide (Fig. 1). Its purity and concentration were tested with Cary 100 Cone system (Li et al. 2003).

PCR Amplification

PCR amplification was performed in a 25 µL reaction volume containing 40 ng genomic DNA, 0.2 mM dNTP at 200 µM final

concentration, 2.5 μ L 10 \times PCR buffer, 40 ng primer, 2 mM $MgCl_2$, 2.0 U of Taq DNA polymerase and ddH₂O. Amplification was carried out in the Gene Amp PCR System at predenaturation at 94 °C for 5 min, then total 40 cycles were run as follows: denaturation at 94 °C for 1 min, annealing at 37 °C for 1 min, extension at 72 °C for 1 min. After the final cycle, reaction mixtures were incubated for a further extension at 72 °C for 10 min. The amplification products were run in 1.3% agarose gel containing ethidium bromide (0.3 μ g/mL) in TBE buffer (89 mmol/L Tris-Hcl, 89 mM boric acid, 10 mM EDTA, pH 8.3). The gels were electrophoresed at 40 V for ~2 h and photographed.

Data Analysis

PCR amplified DNA bands were recorded as 1 for presence and 0 for absence. Using the "0, 1" matrices, the percentage of polymorphic loci (P), average genetic heterozygosity (H) and genetic distance (D) of three species of abalone were calculated using Popgen32 software:

P = polymorphic fragments/total amplified fragments

$D = -\ln \frac{J_{xy}/J_x J_y}{J_x J_y}^{1/2}$ (Nei & Li 1979). J_x is the average genetic identity between population x and y. J_x and J_y are the average genetic identity of population x and y respectively.

$$H = \sum_{i=1}^n (1 - \sum X_i^2) / n$$

Figure 1. Electrophoresis patterns of DNA. M: λ DNA/Hind III.

(Nei 1978). x_i is the frequency of allele X_i , n is the number of tested loci.

Cluster analysis is based on D with the UPGMA (unweighted pair group method using arithmetic mean).

RESULTS

RAPD Analysis

The screened 20 primers yielded 213 bands ranging from 250–2600 bp and most of them were 500–2000 bp. Each primer gave 0–11 bands for each individual. Every individual had some different bands from the others. Population F had 113 polymorphic bands, Z 93, and B 107. The genetic diversity between Z and B was relatively small whereas there was obvious diversity among F, Z, and B. The band of 600 bp for S01, the band of 278 bp for S02, and the band of 1,400 bp for S14 were specific fragments of population F. S12-900 bp and S12-1400 bp bands were hardly found in Z and B populations, but both were present in F. (Fig. 2 and Fig. 3). It is clear that S1-600 and S14-1400 are polymorphic bands of population F and S6-800 bp is the specific band of Z and B population. S13-750 bp of B is much clearer than that of Z and S5-1500 bp only emerges in B population (Fig. 4).

The percentage of polymorphic loci and the average genetic heterozygosity of every population were calculated according to the statistics of the amplified bands (Table 2).

Genetic Distance & Dendrogram

According to the Nei's expressions, we obtained the genetic distances and the genetic identities among the 3 populations (Table 3). The genetic distances between F and the other two species (0.2998 and 0.02880) are greater than that between Z and B (0.0411). Simultaneously, the genetic identities between Z and B

Genetic identity (above diagonal, Genetic distance (below diagonal))

Figure 5. The phylogenetic relationships among the three species of abalone.

was higher than that between F and Z or B. Based on the genetic distances, a phylogenetic tree was constructed with the UPGMA method (Fig. 5). It showed that Z had much closer relationship with B than with F.

DISCUSSION

The average genetic heterozygosities of populations F, Z, and B were 0.1683, 0.1557, 0.1860 respectively, and the percentages of polymorphic loci were 53.05%, 43.66%, and 48.98%. The average genetic heterozygosity was the average number of all amplified loci, and Nei and Li (1979) suggested that genetic heterozygosity was more appropriate for genetic variation. Among the three populations, Z had a relatively lower genetic diversity than B and F. One explanation for this might be that the samples of Zhangzi Island were cultured and therefore had a relatively high homozygosity. Initially the analyses of genetic diversities on marine mollusca were mostly done by means of enzyme technique (Li et al. 2002, Yang et al. 2000). Later, RAPD analysis became a dominant method due to the fact that the RAPD marker is more sensitive than enzyme analysis. Song et al. (1999) analyzed the genetic diversities of *Penaeus japonicus* and found that the percentage of its polymorphic loci was 54.14% and 0.2157 for the average genetic heterozygosity. Wang et al. (2001) concluded that the percentage of polymorphic loci of *Pseudosclimna crocea* was 18.90% and the average genetic heterozygosity was 0.096. The average genetic heterozygosity of *Penaeus chinensis* is 0.2176 (Shi et al. 1999). Compared with the results with other marine creatures, abalone has an accessible genetic variation. Genetic diversity lays the foundation for creatures to survive and adapt to changing environments. Dropping of genetic variation results in lost of the ability of creatures to adjust to the changing living conditions. Protecting biologic diversity is mainly protecting genetic diversity.

The dendrogram constructed on the basis of the genetic distance indicates the systematic relationships among the 3 populations of abalone. Z and B have a very close relationship and their distance is only 0.0411. The distances between F and Z or B are 0.2898 and 0.2880 respectively. According to the traditional classification, F and Z are 2 species of abalone, and they have large differences in many aspects such as morphology, growth environment and growth rate. Z and B are regarded as the same species,

but different geographical subspecies, and they have similar morphology and living habits. Hence, the result of present RAPD analysis is in agreement with the traditional taxonomy, and it is also identical with Thorp's (1982) viewpoint: two populations whose genetic distance is bigger than 0.15 are different species, and the genetic identity between the same species ranges from 0.2 to 0.8.

The RAPD technique has been gradually used in detection of genetic variability, identification of systematic relationship, etc., due to its advantages: prior knowledge of the molecular biology

(genetic background) of the investigated organisms is not required; the required primers are easy to obtain. Our study again suggests that RAPD is an efficient and sensitive genetic marker. However, RAPD also has its defects: poor repetition and artificial identification of the amplified bands. To get reliable results, it is very important to pay attention to the strictness and consistency of experiment conditions, including DNA extraction, concentration test, PCR reaction system establishment etc. If possible the manipulations for all samples to be compared should be done at the same time.

ABSTRACT *Haliotis discus* and *Haliotis diversicolor* are economically important abalone species in northern and southern China, respectively. Two subspecies have been recognized for each species, namely, *H. discus discus* and *H. discus hannai*, and *H. diversicolor diversicolor* and *H. diversicolor supertexta*. The aim of this study is to elucidate the genetic differences between the two species, and their subspecies, based on sequence analyses of nuclear DNA (first internal transcribed spacer of ribosomal RNA (*ITS-1*) and *18S rRNA*) and mitochondrial DNA (*16S rRNA* and cytochrome oxidase I (*COI*) gene). The two species are identical in their *18S rRNA* sequences but differ in their *ITS-1*, *16S rRNA*, and *COI* sequences, with sequence divergence ranging from 9.3% to 18.5%. Sequences of *18S rRNA* are identical between the subspecies of *H. discus*, and those of *H. diversicolor*. For *16S rRNA* and *COI*, there are 0% to 1.4% divergence between the two *H. discus* subspecies, and 0.2% to 0.6% divergence between the two *H. diversicolor* subspecies. Phylogenetic analyses show that the individual haplotypes of each subspecies are not separated to distinct clades, indicating high genetic similarity between the subspecies of both *H. discus* and *H. diversicolor*.

KEY WORDS: genetic divergence, abalone, *Haliotis discus*, *Haliotis diversicolor*, subspecies

INTRODUCTION

Haliotis discus Reeve, 1846 and *Haliotis diversicolor* Reeve, 1846 are economically important abalone species in northern and southern China, respectively. Two subspecies have been recognized for each species, namely, *H. discus discus* Reeve, 1846 and *H. discus hannai* Ino, 1952 and *H. diversicolor diversicolor* Reeve, 1846 and *H. diversicolor supertexta* Lischke, 1870 (= *H. diversicolor aquatilis* Reeve, 1846) based on morphologic traits (Chen 1984, Nie 1989, Okutani 2001). There have been limited studies on the genetic differences between the two species and their subspecies. Naganuma et al. (1998) reported the differences in partial *18S rRNA* sequences between the 2 subspecies of *H. discus*. No studies have been reported on the genetic differences between these two subspecies based on mitochondrial DNA. In addition, there are no reports on DNA analysis of the two *H. diversicolor* subspecies. The taxonomic status of the subspecies of *H. discus* and *H. diversicolor* is controversial (Hara & Fijio 1992, Geiger 2000). In particular the genetic differentiation between *H. diversicolor diversicolor* in mainland China and *H. diversicolor supertexta* in Taiwan is unknown.

Nuclear DNA markers such as *18S ribosomal RNA (18S rRNA)* and the first internal transcribed spacer of *rRNA (ITS-1)* and mitochondrial DNA markers such as *16S ribosomal RNA (16S rRNA)* and cytochrome *c* oxidase subunit I gene (*COI*) have been extensively used in resolving genetic relationships of various taxonomic groups in the species level (Avisé 1994, Hillis et al. 1996). This study reports the genetic divergence of the four abalone taxa based on sequence analyses of the above mentioned genes.

MATERIALS AND METHODS

Sample Collection and DNA Extraction

Haliotis discus discus were collected from Putian County, Fujian Province, China. The cultured stock was introduced from

Japan. *Haliotis discus hannai* were collected from an abalone farm in Qingdao, Shandong Province. Wild *Haliotis diversicolor diversicolor* were collected from Sanya, Hainan Province. *Haliotis diversicolor supertexta* were collected from an abalone farm in Dongshan County, Fujian Province. The stock was introduced from Taiwan. Total DNA was extracted from pleopod muscle using QIAamp DNA Mini Kit (QIAGEN) according to the tissue protocol.

Polymerase Chain Reaction and DNA Sequencing

Segments of *18S rRNA*, *ITS-1*, *16S rRNA*, and *COI* were amplified from two individuals of each taxon using polymerase chain reaction (PCR). Partial *18S rRNA* was amplified using primers 21-mer and 19-mer (Medline et al. 1988) following the conditions as described by Naganuma et al. (1998). PCR conditions for *ITS-1* amplification using primers sp-1–3 and sp-1–5 followed Chu et al. (2001). *16S rRNA* was amplified using the primer pair 16Sar and 16Sbr (Simon et al. 1994). PCR reaction cycling program was as follows: 2 min at 94 °C, 38 cycles of 30 sec at 94 °C, 45 sec at 45 °C, 90 sec at 72 °C, and final extension for 5 min at 72 °C. Two primer pairs COI_f and COI_a (Palumbi & Benzie 1991) and LCD1490 and HCO2198 (Folmer et al. 1994), were used for amplifying two regions of *COI* gene. The PCR conditions for amplifying *COI* were the same as those used in *16S rRNA* amplification.

Prior to sequencing, PCR products were purified using the QIAquick PCR purification kit. Double-stranded PCR products were sequenced from both directions using both of the primer pairs and ABI PRISM dRhodamine Terminator Cycle Sequencing Ready Reaction Kit. The products were purified and loaded onto an automatic sequencer (ABI PRISM 3100 Genetic Analyzer) for analysis.

Data Analysis

Sequences of each gene were aligned by eye with the aid of ABI Sequence Editor 1.0.3. The sequence of each gene in an individual was confirmed by reference to data from both strands

*Corresponding author. E-mail: kabouchu@cuhk.edu.hk

except the *18S rRNA*. MEGA2 (Kumar et al. 2001) was used in calculating sequence divergence and constructing neighbor-joining phylogenetic trees with 500 bootstrap replicates.

RESULTS

All sequences determined in this study have been deposited in the GenBank database (accession numbers: AY319420-319447). The size of PCR products from *18S rRNA* amplification was approximately 1800 bp, with 620 bp determined from the 5' end and 698 bp determined from the 3' end. The sequences determined in the four abalone taxa were identical.

For *ITS-1*, *16S rRNA*, and *COI* the sequence of each gene was confirmed with reference to data from both strands. The size of PCR product from *ITS-1* amplification was approximately 350 bp. While 340 bp of *ITS-1* were determined from the two subspecies of *H. diversicolor*, 307 bp were determined from the two subspecies of *H. discus*. The sequences from the two individuals in each taxon were identical (Table 1). There was 0.6% (2 bp) sequence divergence between *H. discus discus* and *H. discus hamai*, whereas the sequences from *H. diversicolor diversicolor* and *H. diversicolor supertexta* were identical. The sequence divergence of *ITS-1* between *H. discus* and *H. diversicolor* was 15.9%.

The size of PCR product from *16S rRNA* amplification was approximately 560 bp. While 526 bp of *16S rRNA* were determined from the two subspecies of *H. discus*, 531 bp were determined from the two subspecies *H. diversicolor*. There was 9.4% to 9.6% sequence divergence between *H. discus* and *H. diversicolor*. The sequences of *16S rRNA* between the two *H. discus discus* individuals were identical, whereas for *H. discus hamai*, the sequence of one of the individuals was identical to that of *H. discus discus*, and exhibited 0.4% (2 bp) divergence from the other sequence. There was 0.4% (2 bp) sequence divergence between the two individuals of *H. diversicolor diversicolor*, and also between individuals of *H. diversicolor supertexta*. Between *H. diversicolor diversicolor* and *H. diversicolor supertexta*, the sequence divergence was 0.2% to 0.6% (1–3 bp).

The size of PCR products from *COI* was approximately 680 bp using the primers COII/COIa and 700 bp using LCD1490/HCO2198. In the four taxa, 639 bp of *COI* were determined from the COII/COIa products and 709 bp were determined from the LCD1490/HCO2198 products. The two overlapping segments were combined to a length of 1,272 bp for analysis. There was 17.5% to 18.5% sequence divergence between the two species. Between the two *H. discus discus* individuals, there was 0.6% (7 bp) sequence divergence whereas there was 0.5% (6 bp) sequence divergence between the two *H. discus hamai* individuals. There

was 0.6% to 1.4% (7–18 bp) sequence divergence between two subspecies *H. discus*. The sequence divergence between the two subspecies (*H. discus discus* and *H. discus hamai*) was smaller than that of the sequence divergence between each individual of *H. discus discus*. The sequence divergence was 0.6% (8 bp) between the two *H. diversicolor diversicolor* individuals, and 0.6% (7 bp) between the two *H. diversicolor supertexta* individuals. There was 0.3% to 0.6% (4–8 bp) sequence divergence between the two subspecies of *H. diversicolor*.

Figure 1 shows the neighbor-joining (NJ) phylogenetic trees of the four abalone taxa based on *ITS-1*, *16S rRNA*, and *COI* analyses. Trees constructed based on each of the three genes clearly separated the two species (Fig. 1A to C). In the tree based on *ITS-1* sequence (Fig. 1A), the two subspecies of *H. discus* was clustered into two different clades with over 60 bootstrap support but the two *H. diversicolor* subspecies did not group separately. In the trees based on *16S rRNA* and *COI* (Fig. 1B and C), each of the four taxa did not cluster together, except in the *COI* tree the two *H. discus discus* individuals clustered together. To enhance the phylogenetic signals, the data sets of the three genes were combined for analysis (Fig. 1D). In this tree, the two *H. discus discus* individuals clustered into a single clade with 97 bootstrap support, whereas individuals of the other taxa did not cluster together.

DISCUSSION

18S rRNA is one of the nuclear DNA markers often used for investigating the phylogenetic relationship and evolutionary history of various species. In this study, the partial *18S rRNA* sequences (1308 bp) determined in *H. discus* and *H. diversicolor* are identical. The 3' sequence of the *18S rRNA* segment obtained is identical to that of *H. discus hamai* (390 bp compared, Naganuma et al. 1998; GenBank Accession No. D88571). However, the sequence exhibits 0.5% (2 bp) divergence when compared with the sequence of *H. diversicolor diversicolor* (390 bp compared; D88572) reported by Naganuma et al. (1998). It is unclear why the sequences of *H. discus discus* are different between the two studies. Yet it should be pointed out that not only the *18S rRNA* sequence determined in the present study is identical in the four taxa studied, but it is also identical to that of *H. tuberculata* Linnaeus, 1758 (390 bp compared, AF120511) and exhibits 99.0% homology with the sequence from *H. madaka* (Habe, 1977) (390 bp compared, D88573). Moreover, the 5' sequence of the *18S rRNA* segment obtained from the present study shows 99.8% and 99.3% homology to those of *H. tuberculata* (466 bp compared, AF120511) and *H. rufescens* Swainson, 1822 (445 bp compared, L78885) respectively. The small genetic differences (<1%) be-

tween these taxa in *18S rRNA* indicate that this gene is quite conserved among abalone taxa. Therefore, *18S rRNA* is not an appropriate marker in discriminating abalone taxa at the species level, although it may serve as a good marker for phylogenetic studies at higher systematic levels.

Haliotis discus discus and *H. discus hannai* are recognized to be two subspecies because the ridges on the shell are thin in *H. discus discus* and relatively thicker in *H. discus hannai*. However, a survey on wild abalone, hatchery-reared abalone seed, and adult abalone from sea ranching (Kobayashi et al. 1992) and growth experiments on the two subspecies under different temperature regimes (Hara 1992), show that the morphologies of the two abalone taxa vary with environmental conditions, particularly temperature. Under low temperature or unstable culture conditions, the morphologic features of *H. discus discus* become similar to those of *H. discus hannai*. Under high temperature or relatively stable growth conditions, the morphologic features of *H. discus hannai* become similar to those of *H. discus discus*. Based on the analysis of 12 allozymes, Hara and Fijio (1992) suggested that the two subspecies could not be separated and their morphologic differences are related to the environmental factors in different localities. In the present study, the two subspecies cannot be distinguished from each other based on *18S rRNA*, *16S rRNA*, and *COI* sequence analyses. Their *ITS-1* sequences only differ by 0.6%, indicating low genetic differentiation between these two abalone taxa. In addition, most of the phylogenetic trees do not clearly separate the two subspecies, and thus fail to support the subspecies status of these two abalone taxa.

Similarly, there are only minor morphologic differences between *H. diversicolor diversicolor* and *H. diversicolor supertexta* with the ridges on the shell thicker in *H. diversicolor diversicolor* but thinner in *H. diversicolor supertexta*. Based on our observations, morphologic variations occur among individuals of a population and growth conditions and diet could affect shell morphology of *H. diversicolor* (Wang et al. unpublished data). This is consistent with the observation made by Lü (1978) who concluded that it is difficult to separate the two subspecies. Geiger (2000) indicated *H. diversicolor diversicolor* and *H. diversicolor super-*

texta are synonyms. In the present study, *H. diversicolor diversicolor* and *H. diversicolor supertexta* did not show any distinct differences in their nuclear and mitochondrial DNA sequences. The sequences of *ITS-1*, *16S rRNA* and *COI* of these two subspecies have also recently become available in the GenBank database (Accession Nos. AF296868, AY146396, AY146401, AY146406, AY146397, and AY146402). Comparison with the corresponding sequences obtained from the present study show that the differences are within 0% to 0.34% from each other. The *ITS-1* sequences are identical to those from the present study. There was 0.2% to 0.9% (532 bp compared) and 0.4% to 0.6% (544 bp compared) divergence in *16S rRNA* and *COI*, respectively. Our phylogenetic analyses based on the three genes show that individuals of each of the two subspecies never cluster together. In addition, a parallel study in our laboratories based on AFLP showed there are no diagnostic bands between the two subspecies (Wang et al. 2004, this issue). These results suggest that *H. diversicolor diversicolor* and *H. diversicolor supertexta* are possibly not genetically distinct, thus putting their subspecies status in doubt.

Results from the present study show a lack of genetic divergence between the subspecies of *Haliotis discus* or *Haliotis diversicolor* based on sequences analyses of the four commonly used nuclear/mitochondrial DNA markers. Analysis of other more variable markers such as mitochondrial DNA control region (Chu et al. 2003) should be performed to investigate the genetic differentiation of the four abalone taxa over their geographical range (see, for example, Sites & Crandall 1997) to elucidate their evolutionary relationship and taxonomic status.

ACKNOWLEDGMENTS

The authors thank Dr. Fuhua Li (Institute of Oceanology, Chinese Academy of Sciences) for collecting specimens of *Haliotis discus hannai* used in this study. The work described in this article was fully supported by grants from Hi-Tech Research and Development (863) Program of China (Project nos. 2001AA620108 & 2003AA603240), and an AoE Fund from The Chinese University of Hong Kong.

ABSTRACT Amplified fragment length polymorphism (AFLP) technology was used to reveal genetic variations and divergence of *Haliotis discus* and *H. diversicolor*, the two economically important abalone species in China. Three sets of selective primers were used for amplification, and 350 bands ranging in size from 80 bp to about 500 bp were scored. The mean percentages of polymorphic bands in the four taxa varied from 51.7% to 62.7%. Similarity indices and genetic distances between individuals of the same species were greater than 0.8 and smaller than 0.2, respectively, whereas the values among individuals of different species were smaller than 0.3 and greater than 1.2, respectively. AFLP profiles of the two abalone species were distinct and could be used for species identification. Specific AFLP bands were also identified for discriminating the two subspecies of *H. discus*. Yet no diagnostic bands were found to differentiate the two subspecies of *H. diversicolor*. The lack of genetic divergence between these two subspecies supports results from a parallel study based on nuclear and mitochondrial DNA sequence analyses. We suggest that the subspecies status of *H. diversicolor diversicolor* and *H. diversicolor supertexta* is questionable. Results of this study are applicable to resource management and future genetic improvement of the two abalone species in China.

INTRODUCTION

Haliotis discus Reeve, 1846 and *Haliotis diversicolor* Reeve, 1846 (Mollusca; Gastropoda; Orthogastropoda; Vetigastropoda; Haliotoidea; Haliotidae; *Haliotis*) are two economically important abalone species that are extensively cultured in China and Japan (Chen 1984). Based on morphologic characters, two subspecies have been identified from each species (Chen 1984, Nie 1989, Okutani 2001). They are *H. discus discus* Reeve, 1846 and *H. discus hannai* Ito, 1952, and *H. diversicolor diversicolor* Reeve, 1846 and *H. diversicolor supertexta* Lischke, 1871 (also named *H. diversicolor aquatilis* Reeve, 1846). However, analyses based on sequences of mitochondrial and nuclear DNA markers show that the subspecies of each species are not genetically distinct, although the difference between the two species is evident (Wang et al. 2004b, this issue). Because the taxonomic status of the subspecies of *H. discus* and *H. diversicolor* is controversial, we aim to further elucidate any genetic differences between these taxa using molecular markers with a higher resolving power.

AFLP is a powerful technique applicable for genomic DNA fingerprinting (Vos et al. 1995). It has a higher resolving power and sensitivity than RAPD analysis in revealing allelic polymorphism (Barker et al. 1999) and thus has been suggested to be one of the appropriate techniques for revealing the genetic variation within species. This technique has been widely applied in studies of genotyping, population differentiation, and genetic diversity for a wide variety of organisms (Liu et al. 1998, Lerceteau & Szmidt 1999, Mueller & Wolfenbarger 1999, Seki et al. 1999, Keiper & McConchie 2000, Wang et al. 2000). In the present study, the genetic variation and divergence within and between the two abalone species *H. discus* and *H. diversicolor* were investigated using AFLP technique. For breeding purpose and genetic resource management, it is essential to clarify the genetic variation and relationship of these two commercially important taxa.

MATERIALS AND METHODS

Sample Collection and DNA Extraction

Specimens of *H. discus discus*, *H. discus hannai*, *H. diversicolor supertexta*, were collected from abalone farms in Putian, Fujian Province (introduced from Japan), Qingdao, Shandong Province, and Dongshan, Fujian Province (introduced from Taiwan), China, respectively. Specimens of *H. diversicolor diversicolor* were collected from the wild stock in Sanya, Hainan Province. The specimens were either preserved in 95% ethanol or stored in -80°C prior to analysis. Total DNA was extracted from foot muscle (20–25 mg) using proteinase-K digestion and DNA binding columns (QIAGEN QIAamp DNA Mini Kit) according to the manufacturer's instructions. The quality of extracted DNA was assessed using 1.0% agarose gel electrophoresis, and the DNA concentration was measured with an UV spectrophotometer (Hitachi U-2001).

AFLP Reactions

Procedures and reagents for AFLP analysis were applied as described in Vos et al. (1995). AFLP banding patterns were visualized on 5% denaturing polyacrylamide gel using silver staining technique. DNA templates for AFLP reactions were generated by restriction digestion and ligation. About 100 ng of total DNA was digested with 5U of *EcoRI* and *MseI* (New England BIOLABS) in 1X NE buffer2 at 37°C for 2 h. The digested DNA fragments were ligated with 2.5 pmol of *EcoRI* and 25 pmol *MseI* adapters in a reaction mixture containing 0.25 mg BSA, 5 pmol ATP, 0.04U T4Dnase, and 10X NE buffer2 at 37°C for 6 h. The ligated DNA fragments were preamplified using a MJ Thermocycler (PTC-100) with a pair of primers containing a single selective nucleotide. The preamplification PCR reaction was conducted at an annealing temperature of 53°C for 30 sec. The 20- μL PCR product mixture was diluted 10-fold with distilled water and used as templates for the subsequent selective PCR amplification. The selective amplifica-

Numbers of amplified bands scored and polymorphic bands observed from AFLP analysis of 4 taxa of *Haliotis* using 3 sets of selective primers.

Taxa	No. of Specimens	Total No. of Bands	Polymorphic Bands		No. of Genotypes
			No.	%	
<i>H. discus discus</i>	10	231	145	62.7	10
<i>H. discus hannai</i>	8	205	106	51.7	8
<i>H. diversicolor diversicolor</i>	10	195	107	55.0	10
<i>H. diversicolor supertexta</i>	10	196	112	57.1	10

tion was performed using 3 pairs of primers (*E*-AAG/*M*-CGA, *E*-AGG/*M*-CTG and *E*-AGC/*M*-CTT).

Gel Electrophoresis and Silver Staining

After selective amplification, the PCR products were mixed with 10 μ L AFLP loading buffer (99% formamide, 10 mM EDTA, 0.05% bromophenol and 0.05% xylene cyanol). The product mixtures were denatured and concentrated at 90°C for 25 min, and cooled down in an ice bath immediately after denaturation. A 5% denaturing polyacrylamide gel (4.75% acrylamide, 0.25% bis acrylamide, 7 mol \times 1⁻¹ urea and 0.5X TBE) was prerun at 145 W for 30 min. Each well was loaded with 2.5 μ L of sample. The gel was electrophoresed in a BioRad Sequi-Gen GT DNA sequencing cell (38 \times 50 cm) at 110 W and 50°C for 2.5 h.

Bands on the gel were visualized using silver staining method derived from Merrill et al. (1979). After electrophoresis, the gel was fixed in 1% ethanoic acid for 30 min. The fixed gel was rinsed in distilled water and stained with a mixture of 0.2% silver nitrate and 0.007% benzene sulphonic acid for 30 min. The stained gel was rinsed again and immersed in a developing solution (2.5% sodium carbonate, 0.037% formaldehyde, 0.002% sodium thiosulphate). When the bands became clear, the development was stopped with 1% ethanoic acid. The bands were scored using the Gel Imaging Analyzing System (Kodak Digital Science, EDAS-120) and the band sizes were estimated with a standard AFLP DNA ladder (Invitrogen, Life Technologies).

Data Analysis

AFLP bands were scored for presence (1) or absence (0), and transformed into 0/1 binary character matrix. Based on the binary matrix, genotypes, percentage of polymorphic bands, similarity indices, and genetic distance were obtained. Similarity indices were calculated using the formula $S = 2N_{ab}/(N_a + N_b)$ (Nei & Li 1979), where N_a and N_b are the number of bands in individuals a and b, respectively and N_{ab} is the number of shared bands. Genetic distances were computed using the formula $D = -\ln S$ (Nei & Li 1979). For the calculation of the above values, we have developed a Microsoft Excel-based BASIC program (AFLP Data Analyser v1.3). Cluster analysis based on UPGMA was conducted using the software MEGA 2 (Kumar et al. 2001) based on the distance matrix.

RESULTS

AFLP was performed using three pairs of selective primers on a total of 38 individuals belonged to four abalone taxa. A total of 350 different bands ranged from 80 to 500 bp in size were scored. The number of bands generated from a single individual varied

from 116 to 163. Because no two individuals shared exactly the same banding pattern, the number of genotypes identified was the same to the number of individuals used in the study (Table 1). The number of bands generated from each taxon varied from 195 to 231 and the percentage of polymorphism ranged from 51.7% (in *H. discus hannai*) to 62.7% (in *H. discus discus*).

A representative AFLP fingerprint from the amplification using one of the primer sets (Fig. 1) shows that the fingerprint was quite similar among individuals of the same species but distinct between different species. Among the 350 bands scored, only 10 bands (2.9%) were shared among all individuals of the four taxa. There were 79 bands common to all individuals of *H. discus*, constituting 32% of the total number of bands scored in this species. On the other hand, 77 bands were common to all *H. diversicolor*, accounting for 36% of the total number of bands scored in this species. There were 41 bands specific to all individuals of *H. discus* but not found in *H. diversicolor*, and 34 bands were specific to *H. diver-*

TABLE 2.

Comparison of similarity index (above diagonal) and genetic distance (below diagonal, in parentheses) within and between taxa estimated by AFLP banding pattern in the four taxa of *Haliotis* abalone.

	<i>H. discus discus</i>	<i>H. discus hannai</i>	<i>H. diversicolor diversicolor</i>	<i>H. diversicolor supertexta</i>
<i>H. discus discus</i>	0.8295 (0.1870)	0.7756	0.2645	0.2600
<i>H. discus hannai</i>	(0.2542)	0.8484 (0.1645)	0.2510	0.2404
<i>H. diversicolor diversicolor</i>	(1.3299)	(1.3825)	0.8484 (0.1644)	0.8348
<i>H. diversicolor supertexta</i>	(1.3470)	(1.4255)	(0.1841)	0.8401 (0.1743)

sicolor. Some of these bands are indicated in Figure 1. These species-specific bands could be used for the development of molecular markers applicable in the identification of these two species of abalone. Six diagnostic bands were also identified between *H. discus discus* and *H. discus hannai*, with three specific to each of the taxa. Yet for *H. diversicolor*, no bands specific to each of the subspecies could be identified.

The similarity indices and genetic distances within or between the four taxa of abalone based on AFLP banding patterns are shown in Table 2. The similarity indices between individuals of the two abalone species were all lower than 0.3, with genetic distances greater than 1.3. The mean similarity index between individuals of *H. discus discus* and *H. discus hannai* (0.78) was considerably lower than those among individuals of the same subspecies. It is evident that the two subspecies of *H. discus* are genetically distinct. However, the similarity index and genetic distance between individuals of *H. diversicolor diversicolor* and *H. diversicolor supertexta* were very similar to values among individuals of the same subspecies, suggesting a lack of genetic divergence between these two taxa.

A phylogenetic tree of the 38 individuals of the four abalone taxa was constructed using UPGMA method (Fig. 2). Individuals of *H. discus discus* and *H. discus hannai* were separated into two distinct clusters but individuals of *H. diversicolor diversicolor* or *H. diversicolor supertexta* did not cluster together.

DISCUSSION

AFLP technique is a highly effective method for examining genetic polymorphism. It does not require any prior sequence information of the species under study and a large number of loci can be generated from a small amount of DNA. Due to its high level of polymorphism, the technique is appropriate to assess organisms with low level of genetic divergence. It has extensively been applied in genetic studies in diverse groups of organisms (Liu et al. 1998, Lerceteau & Szmidt 1999, Mueller & Wolfenbarger 1999, Seki et al. 1999, Keiper & McConchie 2000, Wang et al. 2000, Nicholas et al. 2001, Ogden & Thorpe 2002). In the present study, we identified 195 to 231 different bands from a single abalone taxon by using three primer sets in the four taxa. Each primer set generates 65 to 77 bands from a single taxon, with polymorphism higher than 50%. Further, AFLP patterns of the individuals differed from each other, and the pattern from a single primer set could be used to distinguish all the individuals from the same taxon. Previous studies, based on analyses of allozymes and RFLP of mtDNA, suggest low genetic diversity in abalone populations,

particularly the cultured stocks (Fujino 1978, Smith & Conroy 1992). No genetic variations were found in *H. discus hannai*, *H. discus discus*, and *H. diversicolor supertexta* in a recent study in our laboratory using 12 allozyme loci and 15 individuals of each taxon (Ke et al. 2003). Yet, more than half of the AFLP bands scored in the present study were found to be polymorphic (the same specimens of *H. discus discus* and *H. diversicolor supertexta* were used in both studies), indicating AFLP as a more effective approach than allozyme analysis in detecting genetic diversity in abalone. Moreover, the results suggest that there are no differences in genetic diversity between the wild stock of *H. diversicolor*

Figure 2. UPGMA dendrogram of the four taxa of *Haliotis* abalone based on distance matrix from AFLP analysis (Table 2).

diversicolor and the cultured stocks of the other three taxa. It is difficult to distinguish whether the wild stock of *H. diversicolor diversicolor* exhibits low genetic diversity due to over-fishing, or the cultured stocks of the other taxa do not suffer from a reduction of genetic diversity. Further studies on genetic differentiation among abalone populations are needed to understand the extent of genetic polymorphism in wild stocks, as well as effect of aquaculture on genetic diversity of abalone. Nevertheless, the present study establishes AFLP as the appropriate method in elucidating and monitoring genetic polymorphism in abalone.

AFLP can be applicable in discriminating different species or subspecies but also elucidating their evolutionary relationships (Tsoi et al. 2003, Wang et al. 2004a). The present study shows that the difference in AFLP banding pattern between *H. discus* and *H. diversicolor* is apparent, giving a genetic distance of higher than 1.3 between the two species. Our phylogenetic analysis also shows that the individuals of these two taxa are clearly separated into two clusters. The results are consistent with the analyses based on morphologic traits or mitochondrial DNA (Wang et al., 2004b, this issue), thus indicating AFLP technique as a potentially useful method for species identification and phylogenetic analysis among species. We have isolated some of the AFLP bands specific to a particular abalone taxon for sequencing analysis and the development of sequence tagged sites (STS) markers. These markers will be most useful for the genetic identification and breeding studies of the abalone taxa under study.

Haliotis discus discus and *H. discus hannai*, and *H. diversicolor diversicolor* and *H. diversicolor supertexta* have been designated as subspecies of their respective species based on morphologic traits (Chen 1984, Nie 1989, Okutani 2001). Results from the present study show that AFLP banding patterns of *H. diversicolor diversicolor* and *H. diversicolor supertexta* are similar. No bands specific to each taxon could be identified. The genetic distance between these two taxa is similar to that within each taxon. Phylogenetic analysis shows that individuals within each subspecies do not cluster together, suggesting *H. diversicolor diversicolor* and *H. diversicolor supertexta* are genetically similar. Recent studies in our laboratory on these two taxa using eight additional primer sets also support results from the present study using three primer sets. A parallel study on the sequence analysis of nuclear and

mitochondrial (mt) genes (*18S rRNA*, *ITS-1*, *mt 16S rRNA*, and cytochrome oxidase I) also shows a lack of divergence between *H. diversicolor diversicolor* and *H. diversicolor supertexta* (Wang et al. 2004b, this issue). Investigations based on morphologic traits and allozymes also cannot establish differences between these two taxa (Lü 1978, Ke et al. 2003 and unpublished data).

In contrast to our AFLP data on *H. diversicolor*, AFLP analysis on the two subspecies of *H. discus* show that they are genetically distinct. Diagnostic bands could be identified from both *Haliotis discus discus* and *H. discus hannai*, and genetic distance among subspecies is higher than values within subspecies. Phylogenetic analysis also demonstrates that individuals of these two subspecies are separated into two different clusters. Yet it should be noted that nuclear and mtDNA sequence analyses failed to distinguish these two subspecies (Wang et al. 2004b, this issue), showing that AFLP is a more sensitive assay for discriminating genetic divergence in closely related taxa. Taken together, results from the present study suggest that because the subspecies status of *Haliotis discus discus* and *H. discus hannai* may be warranted, the distinction between *H. diversicolor diversicolor* and *H. diversicolor supertexta* is put into question. The latter conclusion supports Geiger's (2000) assertion that the two subspecies of *H. diversicolor* are synonymous. Yet Hara and Fijio (1992) also argued that divergence of the two subspecies of *H. discus* only represents population differences. It should be pointed out that only a single population from each of the four abalone taxa was included in the present study. A more extensive study based on population aggregation analysis (Davis & Nixon 1992) over the geographical range of these abalone taxa is necessary to establish the presence or absence of genetic divergence of the subspecies in question.

ACKNOWLEDGMENTS

The authors thank Dr. Fuhua Li (Institute of Oceanology, Chinese Academy of Sciences) for collecting the specimens of *Haliotis discus hannai* used in this study. The work described in this article was fully supported by grants from Hi-Tech Research and Development (863) Program of China (Project nos. 2001AA620108 & 2003AA603240, and an AoE Fund from The Chinese University of Hong Kong).

¹Iwate Fisheries Technology Center Heita Kamaishi Iwate 026-0001 Japan; ²Iwate Inland Fisheries Technology Center Yoriki Matuo Iwate 028-7302 Japan; ³Laboratory of Integrate Aquatic Biology, Marine Field in Field Science Center, Graduate School of Agricultural Science, Tohoku University Onagawa Miyagi 986-2242 Japan

ABSTRACT Shell color variation is one of the more interesting phenomena in abalone breeding. Especially, the identification of inheritable shell color will be a useful visual genetic marker. Bluish shell colored individuals were discovered in one full-sib family A out of nine families (A to I) in the Pacific abalone, *Haliotis discus hannai*. The segregation of the variant (bluish) type and the normal (greenish) type was 13:27, suggesting the existence of a recessive allele at a single locus. To clarify the genetic control of shell color variation, mating experiments were designed for the F₂ generation among the bluish-type and greenish-type individuals within the full-sib family A. All individuals were of the greenish type in the three full-sib families between greenish-type female and greenish-type male, whereas all individuals were of the bluish type in the six full-sib families between bluish-type female and bluish-type male. All individuals were of the greenish type in the four full-sib families between bluish-type female and greenish-type male, whereas segregation of the greenish type and the bluish type was observed in the two full-sib families between greenish-type females and bluish-type males. The observed numbers showed no significant deviation from expected numbers calculated under Mendelian segregation (1:1) in each family. These results indicate that the bluish and greenish shell color variant types are controlled by a recessive allele (*b*) and a dominant allele (*G*) at a single locus. Therefore, the genotype of parental individuals (f1 and m1) of the full-sib family A is estimated as *G/b*. To elucidate the genetic control of shell color variation, further mating experiments were designed for the F₂ generation within and between full-sib families D and G in which the male parent (m1) is common with the family A. As expected, segregation of the bluish and greenish types was observed in the two full-sib families out of 13 families. The observed numbers showed no significant deviation from expected numbers calculated under Mendelian segregation (3:1). These results support the elucidation of the genetic control of shell color variations described in the present study.

KEY WORDS: abalone, *Haliotis discus hannai*, shell color variation, mating experiments

INTRODUCTION

Shell color variation is one of the most interesting phenomena in shellfish aquaculture. The genetic basis of shell color variation was reported in *Urosalpinx cinerea* (Cole 1975), *Mytilus edulis* (Newkirk 1980), *Thais emarginata* (Palmer 1985), *Pinctada fucata martensii* (Wada & Komaru 1990), *Fulvia mutica* (Fujiwara 1995), and *Ruditapes philippinarum* (Kishioka et al. 1997). Cole (1975) reported that in mating experiments a single-locus genetic model controlled three types of shell color variation in *Urosalpinx cinerea* with complete dominance. Similarly, Newkirk (1980) reported that at least two types of shell color variants occurs in *Mytilus edulis* and is determined by a simple genetic mechanism.

The Pacific abalone (*Haliotis discus hannai*) is a commercially valuable species. The creation of artificial culture strains has been expected to allow discrimination from the wild individuals. Visual genetic markers, such as color variation, are, therefore, desired. Shell color variation has been reported in a number of abalone species (Ino 1952, Sakai 1962, Ogino & Ohta 1963, Sibui 1971), however, the variation has been shown to be dependent on dietary differences. In the Pacific abalone, *Haliotis discus hannai*, Sakai (1962) observed bluish-green, green, greenish-brown, and brown shell colors produced by different alga diets. Ogino and Ohta (1963) reported that a green colored shell may be obtained through an artificial diet, however there has been limited research to determine the genetic basis of shell color variation in the Pacific abalone.

In an attempt to underpin the genetic control of traits such as color variation, the discovery of color variation and detection of color types are first needed, followed by segregation of phenotypes

in offspring produced by systematic mating experiments under the same rearing conditions. In the present study, bluish shell color-variant individuals were discovered in one full-sib family (one male crossed with one female). Systematic mating experiments were then undertaken and segregation of the color types were analyzed in the offspring of several mating experiments in an attempt to understand the genetic control of shell color variation in the Pacific abalone.

MATERIALS AND METHODS

Detection of the Color Types

Shell color types were visually divided into two groups, one of which was a greenish type (green to bluish-green but not light and purplish blue) and the other a bluish type (light-blue to purplish-blue with greenish color) as shown in Figure 1. Determination of shell color types of the offspring in experiments I, II, and III were carried out using individuals of more than 17 mm of shell length at the ages of 229, 222, and 245 days after fertilization, respectively. Because, shell color types are clearly divided into two types at more than 17-mm shell length. Any changes of shell color types were not observed after the detection.

Mating Experiments

Figure 2 shows the mating experiment system used in the present study. Two populations were collected from the coastal water of Aomori (41°N, 141°E) and Iwate (40°N, 142°E) Prefectures in the northeastern part of Japan. Aomori population was stocked during two generations, and Iwate population was stocked during three generations before using. One greenish fe-

Figure 1. Typical shell color variation of *Haliotis discus hannai* of mating experiment I and II. 1; greenish shell color type of family A of mating experiment I. 2; bluish shell color type of family A of mating experiment I. 3; greenish shell color type of family AA12 of mating experiment II. 4; bluish shell color type of family AA12 of mating experiment II. Individuals of 1 and 2 are approximately two years old, 3 and 4 are approximately 17 months old. Scale bar = 10 mm.

male (Pf) of the Aomori population and one greenish male (Pm) of the Iwate population were used for producing the parental generation (P1) during 1996. Three greenish females and three greenish males of the P1 generation were used for producing the nine full-sib families of the first offspring generation (F1) in September 1999 as shown in mating experiment I.

During mating experiment II, fifteen pair-crosses were produced in August 2001 using the 6 females (3 individuals of the bluish-type and 3 of the greenish-type) and 5 males (3 individuals of the bluish-type and 2 of the greenish-type) from the full-sib family A in which bluish and greenish color types were segregated. Combinations of the crossed individuals were as follows (Fig. 2): bluish-type female × bluish-type male (6 pair), bluish-type female × greenish-type male (4 pair), greenish-type female × bluish-type male (2 pair), and greenish-type female × greenish-type male (3 pair).

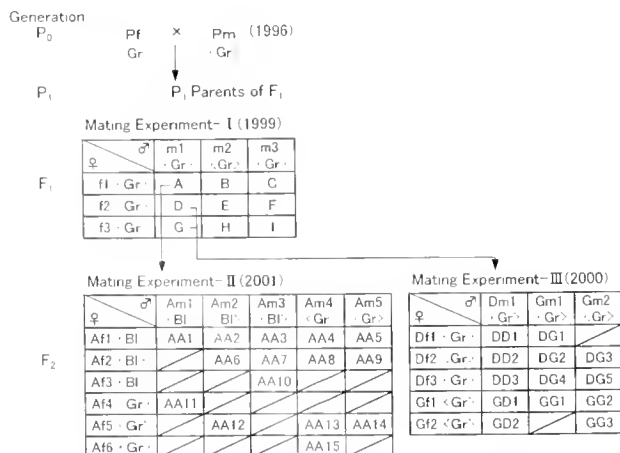

Figure 2. Mating experiment system in the present study. Gr and Bl represent phenotype of greenish-type and bluish-type, respectively.

To elucidate the genetic control of shell color variation, mating experiment III was designed for the F2 generation within and between full-sib families D and G in which male parents are common with full-sib family A. Thirteen full-sib families were produced in November 2000 using five females and three males as shown in Figure 2.

Breeding and Rearing

Individuals of parents for mating were set into the separate containers before spawning. Spawning was artificially induced with ultraviolet light-irradiated seawater. The spawned eggs were separated into several containers for each pair-mating, and fertilized with the sperm of a different male, respectively. After hatching, larvae were reared in the meshed bottom containers for 4 days. Settlements were conducted with wavy-plates, which were covered with *Ulva lens*, and placed into clear plastic 20-L containers. They were reared in a sunny place allowing juveniles to feed on diatoms, which grew on the wavy-plates and the surfaces of the containers. An artificial diet (Cosmo Kaihatsu K.K., Standard type), which usually produced greenish color shells on the Pacific abalone, was given after their shell lengths reached about 10 mm. They were reared in running seawater whose temperature was maintained at almost 20°C during the experiments.

Statistic Analysis

Expected numbers were calculated under Mendelian segregation, assuming that the bluish type was controlled by a recessive allele at a single locus. The χ^2 test was performed for comparison between the observed number and the expected one.

RESULTS

In the present study, the bluish color shell was formed after the artificial diet provided, although it was observed that diatoms and an artificial diet normally formed a greenish color shell. The bluish-type individuals initially formed green shells until their shell length reached about 10–15 mm, therefore around an apex of their shells remained greenish color (Fig. 1). The ranges of shell length determined the shell color types in the mating experiment I, II, and III were 17–36 mm, 17–46 mm, and 17–37 mm. The shell's bluish pigment appeared only on the outer shell surface, though the hues of the pearl layer were not changed.

The results of the mating experiment I are shown in Table 1. Nine full-sib families were obtained and only the greenish type was observed in all families except one. In full-sib family A, phenotypic segregation was observed; that is, 27 were of the greenish type, whereas 13 were the bluish type. The results showed no significant deviation from expected numbers calculated under Mendelian segregation (3:1).

Three females and three males of bluish type, and three females and two males of greenish type were then picked up from full-sib family A, and a total of 15 full-sib families of the F2 generation were produced. The results of the mating experiment II are shown in Table 2. All offspring individuals were of the greenish type in the three full-sib families (AA13, AA14, and AA15) produced by mating between greenish-type females and greenish-type males and in the four full-sib families (AA4, AA5, AA8, and AA9) between bluish-type females and greenish-type males. On the other side, all offspring individuals were of the bluish type in the six full-sib families (AA1, AA2, AA3, AA6, AA7, and AA10) produced by mating between bluish-type females and bluish-type

males. Phenotypic segregation of the greenish type and bluish type was observed in the two full-sib families (AA11 and AA12) between greenish-type females and bluish-type males. The observed numbers showed no significant deviation from expected numbers calculated under Mendelian segregation (1:1) in each family. These results suggest that the bluish and greenish shell color variant types are controlled by recessive allele (*b*) and dominant allele (*G*) at a single locus, and the genotype of parental individuals in the pair-cross A are estimated as *G/b*.

To elucidate the genetic control of shell color variation, further mating experiments (mating experiment III) were designed for the F2 generation within and between full-sib families D and G in

which the male parent (m1) is the same as that of the full-sib family A (Table 3). All individuals in all full-sib families were of the greenish type except the two families. The bluish type appeared in the DG3 and GG3 families. The observed numbers of greenish to bluish individuals each of the DG3 (56:14) and GG3 (85:24) families showed no significant deviation from the expected numbers calculated under Mendelian segregation (3:1).

DISCUSSION

Shell color variations reported in the Pacific abalone are caused by environmental factors, such as natural and/or artificial dietary food. In the mating experiment I of the present study, however, bluish-type individuals were discovered along with the greenish type in one family, even though all individuals in the family have been reared in the same tank (same food and same environment). This suggests that color variations are caused by genetic factors. Moreover, the segregation rate of greenish and bluish types was not significantly different from 3:1, suggesting an existence of dominant (*G*) and recessive (*b*) alleles at a single locus. Also, the genotypes of both parents, f1 and m1, are considered to be *G/b*.

To elucidate this assumption, mating experiments should be conducted between any combinations of color types within family A. Because an abalone spawns a high number of eggs, all combinations could be designed in the same generation and in the same family as in the present study. In mating experiment II, the results of segregation indicated that the assumptions of genotypes are elucidated without any exception. For example, the genotypes of *G/G* and *G/b* would be included in the greenish-type individuals of family A at the proportion of 1:1 in this assumption. As a matter of course, the genotypes of bluish-type parental individuals are estimated as *b/b*. Then, the genotypes of maternal greenish-type individual of family AA11 and AA12 are estimated as *G/b*, because, both families segregated no significant deviation from 1:1.

Similarly, the genotypes of *G/G* and *G/b* would be included in the B, C, D, and G families at the proportion of 1:1. The results of

mating experiment III show that all segregations in 13 combinations from the D and G families are not contradicted under the Mendelian Law assuming a single locus. From the earlier results, genetic color variations observed in the Pacific abalone population, and these color variations are controlled by dominant (*G*) and recessive (*b*) alleles at a single locus.

The color variation of the bluish type has not been observed or reported in the natural resources of abalone around Japan. It could be caused by a low frequency of the allele (*b*), by a newly arisen mutation of allele (*b*), and/or by the low adaptation (low viability) of an individual of homozygote (*b/b*). The clarification of this issue provides a subject for future investigation.

In the present abalone culture, the development of new artificial strains is expected and can be distinguished at a glance. The bluish type shell color variation will be useful for future abalone culture as a visual genetic marker for several breeding studies.

ABSTRACT This experiment was designed to evaluate the genetic resistance to amyotrophia of Japanese abalone (*Haliotis discus discus*) under a mixed rearing environment. Two selected families that had previously shown resistance to abalone amyotrophia as candidates, two nonselected families as controls that had previously not shown resistance, and two hybrid families were used. Individuals from these families were fertilized and mixed immediately after hatching, and then they were raised in a mixed rearing tank at an abalone hatchery during the period of frequent spontaneous occurrences of abalone amyotrophia. Furthermore, we have isolated seven new microsatellite DNA loci for identifying families, and so the six offspring families in the mixed rearing tank could be discriminated unambiguously. The survival ratio of the two selected families was 87% and 93% after the occurrence of mass-mortality caused by abalone amyotrophia, whereas that of the four other families ranged from 0% to 37%. Survival performance among the offspring families was significantly different under the mixed rearing environment. This result suggests strongly that resistance to abalone amyotrophia of juveniles is related to the genetic characters of the spawners. Therefore, this experiment shows that resistance to the disease is a heritable trait, because the two selected families produced offspring with a high survival ratio after the occurrence of abalone amyotrophia.

KEY WORDS: abalone amyotrophia, Japanese abalone (*Haliotis discus discus*), microsatellite, parentage analysis, resistance

INTRODUCTION

Japanese abalones include four species that are economically important for commercial fisheries and as aquaculture resources in Japan, because of their high market value and their high volume of catch. However, the volume of abalone catch has been continuously decreasing for about 30 y (Anon. 2001). Therefore to increase and stabilize the commercial catch of abalone, techniques for mass production of hatchery-produced abalone seed have been developed over the last 20 y and the use of these techniques has been spread throughout the many prefectural hatcheries in Japan. In particular, the mass production of hatchery juveniles of 2 species, *Haliotis discus hannai* and *Haliotis discus discus* that support significant local fisheries, has been well studied. The juvenile production of *H. d. hannai* has increased smoothly year by year, and more than 20 million juvenile abalone were produced in 1999. However, the hatchery juvenile production of *H. d. discus* has been stagnant because mass mortalities of juvenile abalone age 0 y have frequently occurred in many abalone hatcheries, especially during the early summer when the rise in temperature is a serious problem. One of the causes of mass mortality was elucidated as an infectious disease characterized clinically with muscular atrophy and histologically with abnormal cell masses originating from nerve tissue (Nakatsugawa 1990, Momoyama et al. 1999). The disease, due to the amyotrophy of the foot muscle, has been tentatively called abalone amyotrophia. Recently, virus particles from juvenile abalone affected with amyotrophia was isolated (Otsu & Sasaki 1997, Nakatsugawa et al. 1999), however the pathogenicity of the virus has not been proved yet. Furthermore, it was reported that the mortality of juveniles spawned from one pair of parents was significantly lower than that of several other pairs during a spontaneous occurrence of abalone amyotrophia leading to mass

mortality (Okada et al. 1999). This fact suggests that the establishment of abalone families resistant to abalone amyotrophia may be possible using selective breeding.

Mixed rearing is regarded as one of the most effective methods for evaluating genetic traits, because it can minimize confounding genetic traits and environmental factors. In separate tanks, even after careful environmental standardization, environmental effects of an unknown nature are often observed to cause phenotype variation among tanks (Bagley et al. 1994, Herbinger et al. 1999). Microsatellite DNA are well known as hyper-variable genetic markers with a high discriminating power, and are regarded as an invaluable tool in the investigation of parentage analysis of hatchery populations (Herbinger et al. 1995, Blouin et al. 1996, O'Reilly et al. 1998, Perez-Enriquez et al. 1999, Hara & Sekino 2003). Discrimination of families using microsatellite DNA typing makes it possible to evaluate the genetic properties of juveniles from a mixed rearing tank.

We have developed several microsatellite DNA markers for parentage analysis in abalone to establish an evaluation method for genetic traits in mixed rearing tanks. The objective of this study is to ascertain the ability to discriminate experimental families using the developed microsatellite DNA markers and to evaluate the survival performance of the selected families resistant to abalone amyotrophia, after the spontaneous occurrence of mass mortality caused by abalone amyotrophia in the abalone hatchery.

MATERIALS AND METHODS

Six abalone families, *H. d. discus*, were fertilized artificially by pairing of three mature dams and three mature sires (Table 1). Of the six parents used, 3 parents (SD#1, SD#2, and SS#1) were the offspring from two families that had a remarkably higher survival rate than other four families among the six experimental families during an outbreak of abalone amyotrophia at Mie prefectural fish farming center in 1995 (Okada et al. 1999). Moreover, the rela-

Sire	SS#1	SS#1	NS#1	NS#2	NS#1	NS#2

tionship between dam SD#1 and sire SS#1 was full sib, and that of dams SD#2 and SS#1 was half sib. These three parents were used for producing the candidate families resistant to abalone amyotrophy. One dam (ND1#) and 2 sires (NS#1 and NS#2) were non-selected, that is, these abalone parents were drawn randomly from the wild population. There were no relationship among ND#1, NS#1 and NS#2. The family #1 and #2, the family #3 and #4, and the family #5 and #6 were respectively called the selected, hybrid and nonselected families (Table 1). The larval offspring of the six families were mixed immediately after hatching, and were allowed to settle on plastic plates for collecting larvae in one tank. The mixed offspring (49,500 at the beginning of this experiment) were raised from November 1999 to April 2000 at an abalone hatchery of the Misaki Fisheries Co-operative Association, located in Ehime Prefecture of Japan.

To investigate the survival of abalone juveniles of the six mixed families during a spontaneous occurrence of mass mortality caused by abalone amyotrophy, 49,500 juveniles from 6–15 mm in shell length were subsequently reared from April to September 2000 in the experimental 10-ton tank of the Misaki hatchery, where mass mortality due to abalone amyotrophy has continuously occurred for several years. During the experimental rearing period, dead and moribund juveniles were removed almost every day while being observed in the experimental tank; the water temperature was measured and the number of surviving juveniles was calculated. Sampled offspring for parentage analysis were drawn randomly from the live juvenile individuals in May and August, before and after the period of mass mortality respectively. Twenty moribund juveniles were examined histologically during the occurrence of mass mortality, using a light microscope, to confirm if the mortality was caused by abalone amyotrophy.

Genomic DNA was extracted from the foot muscle tissue of the 6 parents and the sampled offspring. We have developed new hyper-variable microsatellite DNA markers for parentage analysis according to the method described in Sekino et al. (2000). Detailed information about the polymerase chain reaction (PCR) amplification protocols are found in Sekino and Hara (2001). Allele sizes were determined relative to a molecular size marker (ALFexpress Sizer 50–500, Amersham Pharmacia Biotech) in combination with the Allelelinks computer software (Amersham Pharmacia Biotech), and alleles were designated according to PCR product size. The relatedness between parents and offspring was examined by matching genotypes at each locus. Survival ratio were estimated from the percentage compositions of the families and total number of offspring reared in experimental tank.

Differences in the composition of families between before and after during mass mortality, and multiple comparisons among each family were done by χ^2 analysis, using the package Statistica (StatSoft Inc, Tokyo).

RESULTS

The estimated number of reared juvenile abalone during the experimental period is shown in Figure 1. Dead juveniles were rarely found in the experimental mixed rearing tank from April to May. After that, mass mortality occurred from June to July, and had almost ceased in August. The total estimated number of juveniles during the period from May to August decreased from 49,500 to 21,500. Decrease in feed consumption, increase in individuals with reduced activity and the appearance of abnormal growth in shell edge were observed in the experimental tank from June to July. However, these symptoms disappeared in August, and it appeared that the abnormal shell edges of individuals had recovered. During the experimental period, the temperature of the mixed rearing tank was 12.9°C to 17.5°C from April to the middle of May and was over 18°C in the end of May. After that, the temperature was continually increased reaching 23.9°C by the end of July, and staying above 24°C in August and September (Fig. 2). Furthermore, abnormal cell masses that were originating from nerve tissue and characteristic in abalone amyotrophy were histologically observed in the foot muscle section of all twenty moribund juvenile abalone, using a light microscope (Fig. 3).

We developed 7 new microsatellite DNA loci, *Hd63*, *Hd201*, *Hd306*, *Hd3105*, *Hd535*, *Hd562*, and *Hd584* from the abalone genome DNA for this experiment, and the PCR primers pertaining to them are given in Table 2. All 7 loci were successfully amplified for 6 abalone parents, and the genotypes of the 6 abalone parents for the 7 microsatellite DNA loci and the number of alleles per locus are listed in Table 3. The number of alleles per locus ranged from 6 to 8 with an average of 6.7, and alleles unique to one parent were found at all loci. Further, all the parents except SD#1 had unique alleles. These microsatellite DNA loci were hyper-variable and stable to analysis.

The parents of individual offspring could be discriminated unambiguously by observations of the unique alleles and/or by comparison of the multi loci genotype for the 7 microsatellite DNA. The parentage inferred from more than two loci agreed perfectly for all analyzed individuals. The families of all offspring were determined precisely by the relatedness between parents and offspring. The percentages and individual number of offspring related to 6 families in May and those of August are shown in Table 4.

The estimated numbers of the selected families (family #1 and

Figure 1. Number of surviving juveniles during the experimental rearing period from April to September.

Figure 2. Changes of water temperature from April to September in this experimental mixed rearing tank.

#2) were 38 and 22 of the 236 analyzed individuals, that is 16.1% and 9.3% respectively of the total mixed families in May, and the percentage compositions of these families had proportionally increased to 34.6% and 18.7% respectively in August. However, the percentage composition of the two hybrid and two nonselected families (family #3, #4, #5, and #6) decreased from May to August. Especially, offspring of the families #6, which (15.3%) was 36 of the 236 analyzed individuals, were not found at all in August. The percentage composition of the 6 families in May was significantly different compared with that in August ($P < 0.01$). Furthermore, on the multiple comparisons among individual number of each family in May and August, significant differences were recognized between the two selected families (family #1 and 2) and the other four families and between the family #6 and the other families ($P < 0.05$). The estimated survival ratio of the selected two families (family #1 and #2), which was calculated based on the total number of offspring reared in the tank and the percentage composition of each family, was more than 80%. However, the estimated survival ratios of the other families were less than 40%.

DISCUSSION

Mass mortality occurred spontaneously from June to July in the experimental mixed rearing tank at the abalone hatchery, and more than half of the juvenile abalone died. This period of mass mortality coincided with the season of mass mortalities reported previously (Nakatsugawa 1990, Momoyama et al. 1999, Okada et al. 1999). Momoyama et al. (1999) histologically examined individual abalone from mass mortalities that occurred in different hatcheries during this period from 1988 to 1996, and they reported that most of mass mortalities were attributable to abalone amyotrophy. The characteristic relation between the occurrence of abalone amyotrophy and ambient water temperature has been reported as follows: the progress of abalone amyotrophy occurs when the water temperature rises to 18°C or higher and is suppressed at more than 23°C (Nakatsugawa 1990, Okada et al. 1999). The range of water temperature of this experimental mixed rearing tank during this mass mortality was consistent with the typical temperature range of mass mortality caused by amyotrophy disease. Unhealthy individual juveniles and with shell edge abnormalities appeared in the experimental tank during this mass mortality period. These symptoms coincide with the characteristics of abalone amyotrophy. Furthermore, abnormal cell masses that were previously reported as characters of abalone amyotrophy (Nakatsugawa 1990, Momoyama et al. 1999) could be observed from all individuals examined histologically. These findings

strongly suggest that the mass mortality during this experimental rearing period was caused by abalone amyotrophy.

The usefulness of microsatellite DNA markers for parentage determination in hatchery populations has been previously reported (Herbinger et al. 1995, Perez-Enriquez et al. 1999, Hara & Sekino 2003). In this experiment, the parent-offspring relationships could be unequivocally identified for all abalone offspring mix-reared from the larval stage onward using the seven new microsatellite DNA loci, and the families of the offspring were accurately discriminated. As a result, the change of the percentage composition of the six families from May to August suggests that the survival of the 2 selected families (family #1 and #2) were significantly better than that of the other 4 families (family #3, #4, #5, and #6) after the occurrence of mass mortality caused by abalone amyotrophy. Juvenile individuals of the six families were reared in the same tank, thus minimizing environmental effects immediately after hatching; therefore their survival performances among families are considered to have been strongly influenced by heritability.

The two selected families were produced from the families that had higher survival rates than the other families after an occurrence of mass mortality caused by abalone amyotrophy, and in this experiment their offspring had survived higher rates than the other families examined. This result suggests that resistance to abalone amyotrophy of the selected families is a heritable trait. However, the estimated survival ratios of the 2 hybrid families (family #3 and #4) that were produced by the dam of the candidate families tolerant to the disease did not differ from that of the one nonselected family (family #5). The family of spawners used as tolerant to abalone amyotrophy in this experiment might not be perfectly fixed genetically. Differences between families for survival ratios in NS#1 and NS#2 of nonselected sires indicate the existence of various degrees of tolerance to abalone amyotrophy in wild abalone populations.

The results of this experiment strongly suggested that resistances to abalone amyotrophy is due to genetic effects. Establishment of a method of experimental infection by isolation of the pathogen of abalone amyotrophy and development of high performance families resistant to the disease, using selective inbreeding techniques, would likely help the problem of mass mortality caused by amyotrophy disease for juvenile production of Japanese abalone, *Haliotis discus discus*.

Figure 3. Muscular section of moribund juvenile abalone during the occurrence of mass mortality. Abnormal cell masses like tumors (★) are observed in muscles organs.

TABLE 4.

Estimated number of offspring and survival ratio of six families reared in tank during the occurrence of mass mortality from May to August. Numbers of offspring (Nt) are estimated based on the genetic markers of microsatellite DNA. Number in parentheses are the percentage of offspring of each family. N(M) and N(A) means the estimated actual number of offspring of families in the tank in May and August based on the percentage respectively.

Family (♀ × ♂)	Estimated Number of Offspring				Estimated Survival Ratio (%) *1 (N(A)/N(M) × 100)
	May Nt (%)	N (M)	August Nt (%)	N (A)	
#1 (SD#1 × SS#1)	38 (16.1)	7970	37 (34.5)	7418	93 ^a
#2 (SD#2 × SS#1)	22 (9.3)	4604	20 (18.7)	4021	87 ^b
#3 (SD#2 × NS#1)	56 (23.7)	11732	22 (20.6)	4429	38 ^c
#4 (SD#2 × NS#2)	27 (11.4)	5643	6 (5.6)	1204	21 ^d
#5 (ND#1 × NS#1)	57 (24.2)	11979	22 (20.6)	4429	37 ^c

ABSTRACT A serious disease occurred in many *Haliotis diversicolor* Reeve farms during 1999 and 2002. The symptoms of the infected abalone were as follows: the pleopod became stiff, its surface became black, and the mantle shrank. All sizes of abalone became infected and mortality was high. A spherical virus was detected in the tissues of the digestive gland, mantle, gill, and intestine of infected animals. It was observed in the cytoplasm and had a diameter about 100–130 nm. Electron microscope examination showed that organelles of infected cells, such as the endoplasmic reticulum; expanded, mitochondria dilated, nuclear membranes dissolved or disappeared, and the edges of the nucleolus swelled. The pathogenicity of the virus was confirmed by experimental infection.

KEY WORDS: virus infection, pathogen, *Haliotis diversicolor* Reeve

INTRODUCTION

Numerous pathogens that cause serious abalone diseases have been reported from different abalone species around the world. Virus-like particles have been observed in the cytoplasm of cells near the nerve trunk of diseased *Haliotis discus discus*, examined with an electron microscope (Otsu & Sasaki 1997). Virus-like particles were also isolated from diseased *H. discus discus* in primary cultures of abalone hemocytes (Nakatsugawa et al. 1999). A spherical virus was detected in "crack shell disease" of *Haliotis discus hannai* (Wang & Li 1997, Li et al. 1998). A similar disease and virus in *Haliotis diversicolor* Reeve were also studied (Wang et al. 2000). The pathogen of an epidemic disease that resulted in mass mortality of *Haliotis diversicolor aquatilis* was studied. Artificially infected abalone revealed that the virus was the lethal pathogen (Song et al. 2000). Three forms of spherical viruses were observed when an epidemic disease of cultured *Haliotis diversicolor supertexta* occurred in Dongshan, Fujian province in 1999 (Zhang et al. 2001).

A bacterial infection was reported in juveniles of red abalone *Haliotis rufescens* (Elston & Lockwood 1983). Mass mortalities of 4-day-old red abalone juveniles were caused by *Vibrio alginolyticus* (Anguiano-Beltrán et al. 1998). A disease of young *Haliotis diversicolor supertexta* was also caused by *Vibrio* spp. The abalone were more easily infected when the temperature was higher (Lee et al. 2001). Other bacteria that have been isolated from *Haliotis discus hannai* are *Vibrio fluvialis*-II (Liu et al. 1995, Nie et al. 1995, Li et al. 1996), *V. campbellii* (Ma et al. 1996), and *Pseudomonas fluorescens* (Ye et al. 1997). Parasites that infect different species of abalone include ciliates in *H. midae* and *H. spadicca* (Botes et al. 1998), kidney Coccidia in *Haliotis rufescens* and *Haliotis midae* (Mouton 2000, Sales & Britz 2000), *Perkinsus* spp. in *Haliotis rubra*, *Haliotis laevigata* (Goggin & Lester 1995), sabellid polychaetes in *Haliotis midae* (Cook 1998, Ruck & Cook 1998, Sales & Britz 2000), and trematode metacercariae in *Haliotis ruber* (Botes et al. 1999).

Haliotis diversicolor Reeve has been increasingly cultured along the southern coastal area of China and has become one of the

most exploited and valuable mariculture species. Mass mortalities have been observed in many commercial farms since a serious disease occurred. All sizes of abalone could be infected, and the mortality may reach 100% in a few days. The culture tanks were filled with foam. The pleopod of the diseased abalone became stiff with a black surface and the mantle and foot shrank. The dead abalone attached to the bottom of the culture cage. Here we study the pathogen, the influence of temperature on its infectivity, and the ultrastructure pathology of the infected abalone.

MATERIALS AND METHODS

Specimens

Diseased abalone, of shell length 4–6 cm, were collected from several commercial farms located in the eastern area of Guangdong Province during 2000–2002.

Healthy abalone, of shell length 4–6 cm, were collected from a farm located in an isolated bay that had never experienced the same disease.

Preparation of Solution for Injection

Ten grams of tissue of diseased abalone was cut into small pieces and homogenized, using a mortar, in the presence of liquid nitrogen. The homogenate was suspended with phosphate-buffered saline (PBS) (Ph = 7.6) (W: W = 1:10) and the suspension was centrifuged at ×2500g for 30 min at 4°C. The supernatant fluid was centrifuged at ×6000g for 30 min at 4°C, and the supernatant fluid was collected and filtered through a 0.22-μm filter membrane.

The suspension from the healthy abalone was prepared using the same procedure.

Challenge Test

Four groups were used for challenge test 1, and were treated as indicated in Table 1. The animals in group 1 were injected with 0.05 mL virus suspension each; group 2 were injected with 0.1 mL virus suspension each; the animals in control group 1 were injected with 0.1 mL suspension of healthy abalone each; the animals in control group 2 were injected with 0.1 mL PBS each. All animals were maintained in the aquaria with recirculating water system at

TABLE 1.

Preparation of challenge test in *haliotis diversicolor* Reeve.

Group	Number of Healthy Abalones	Dose of Injection	Temperature for Maintaining
Group 1	10	0.05 ml virus suspension	17°C
Group 2	10	0.1 ml virus suspension	17°C
Control Group 1	10	0.1 ml suspension of healthy abalone	17°C
Control Group 2	10	0.1 ml PBS	17°C

17°C. The salinity of the water was 30 ppt. The mortality and clinical signs were observed and recorded every day.

Temperature Influence on Disease Outbreak

The abalone were divided into 5 groups with 10 individuals each. They were treated as indicated in Table 2. The animals in group 3, group 4, group 5, and group 6 were injected with 0.1 mL virus suspension respectively; the animals in control group 3 were injected with 0.1 mL PBS. All animals were maintained in aquaria with recirculating water, the salinity of the water was 30 ppt. Mortality and clinical signs were observed and recorded every day.

Transmission Electron Microscopy

The tissues of digestive gland, mantle, gill, and intestine of both naturally and experimentally infected abalone were cut into pieces about 1 mm³ in size, and fixed in 2.5% glutaraldehyde in 0.1 PBS buffer at 7.4. After being washed in PBS buffer for 1 h at 4°C, samples was postfixed in 1% osmium tetroxide in the same buffer at 4°C. The samples were dehydrated in ascending concentrations of ethanol (50% to 100%), and then embedded in Epon812 resin. Ultra-thin sections were cut and stained with uranyl acetate and lead citrate, and examined in a PhilipsCM10 transmission electron microscope.

Negative Stain

Twenty grams of tissue of diseased abalone was cut into small pieces and homogenized using a mortar, in the presence of liquid nitrogen. The homogenate was suspended in phosphate-buffered saline (PBS) (W: W = 1:10) and the suspension was centrifuged at ×6000g for 30 min at 4°C. The supernatant fluid was centrifuged at ×200000g for 60 min at 4°C, and the deposit was resuspended with PBS and stained with 2.5% sodium phosphotungstate (pH 7.0), and then examined in a Philips CM10 transmission electron microscope.

TABLE 2.

Temperature influence on disease outbreak.

Group	Number of Healthy Abalones	Dose of Injection	Temperature for Maintaining
Group 3	10	0.1 ml virus suspension	17°C
Group 4	10	0.1 ml virus suspension	20°C
Group 5	10	0.1 ml virus suspension	23°C
Group 6	10	0.1 ml virus suspension	26°C
Control Group 3	10	0.1 ml PBS	17°C

RESULTS

Challenge Test

Several dead abalone were observed in group 1 and group 2 that were injected with virus suspension within 48 h and all died within 96 h (Table 3). The aquarium was filled with foam, which also occurred when the infection occurred naturally (Fig. 1a). The clinical symptoms of infected abalone were also similar to naturally infected abalone (Fig. 1b). No mortality was recorded in the control groups.

Temperature Influence on Disease Outbreak

The disease outbreak was associated with low temperature (Table 4). All the abalone died within 96 h when the temperature of the water was at 17°C and 20°C. No abalone died when the temperature of water was 23°C or 26°C. All abalone in the control group survived.

Electron Microscopy

Infected cells in the connective tissue showed hypertrophied or irregular shaped nuclei and marginated chromatin (Fig. 1c, d), which indicated the condensation of chromatin and DNA. Some nuclei were highly electron dense. Chromatin was densely packed around the nuclear envelope, and the membrane of the nucleus disintegrated (Fig. 1c). The nucleus collapsed in seriously affected cells. The nuclear membrane totally dissolved, and some highly electron dense material could be seen in the collapsed nucleus (Fig. 1e).

Pathologic changes were observed in the organelles of the infected cells. The endoplasmic reticulum expanded, mitochondria dilated and became irregularly shaped, and mitochondrial cristae shrank or disappeared (Fig. 1f). In the cytoplasm, irregularly shaped spore-like bodies were observed. The bodies appeared to be mineral concretions, composed of numerous alternating electron dense and electron lucent layers (Fig. 2a).

Virus particles were mainly observed in connective tissue cells and occasionally in hemocytes. The particles were circular in shape, 100–130 nm in diameter (Fig. 2b), contained an electron-dense nucleocapsid, and the outer layer was the thick envelope. Between the envelope and nucleocapsid, there was an electron lucent layer about 10–15 nm in thickness. The nucleocapsid was electron-dense and 80–100 nm in diameter. In some cells, numerous virus particles aggregated together and were surrounded by a double-layer membrane (Fig. 2c, d). The virus particles scattered in the cytoplasm in some infected cells (Fig. 2e, f). Figure 3a shows a magnification of the virus particles. Among the aggregat-

ing viruses, there were empty and deformed capsid-like structures (Fig. 2c). These may be abnormally assembled viral proteins. TEM examination revealed that virus particles existed in challenged individuals, but not in nonchallenged ones.

Negative stain showed the virus particle was about 100–130 nm in diameter (Fig. 3b), similar to the size of virus particle observed in ultra-thin section (Fig. 3a).

DISCUSSION

Viruses are some of the most important agents that cause mass mortalities of animals. Viruses reported in marine shellfish include Herpesviridae, Iridoviridae, Papovaviridae, Togaviridae, Retroviridae, Reoviridae, and Paramyxoviridae.

Several viruses associated with the mass mortalities of the host

TABLE 4.
The cumulative mortality of infected abalones at
different temperature

Group	Time (h)				Mortality Rate
	24	48	72	96	
Group 3	0	2	7	10	100%
Group 4	0	4	8	10	100%
Group 5	0	0	0	0	0
Group 6	0	0	0	0	0
Control Group 3	0	0	0	0	0

species have been reported. Irido-like virus attacked the velar epithelium of *Crassostrea gigas* and caused severe hatchery losses (nearly 100%), which usually appeared from March to May, but also occurred throughout the summer (Elston, 1979). Icosahedral DNA virus caused the Portuguese oyster *Crassostrea angulata* Lamarck velar virus disease and hemocyte infection virus disease (HIV), extensive gill erosion corresponding with high mortalities. Gill disease was regarded as one factor in the elimination of the Portuguese oyster from important culture areas on the Atlantic coast of France (Comps 1988). In *Tiostrea chilensis* larvae and spat, the interstitial cells, mantle, and digestive tract of epithelial cells were infected with herpes-like viruses and infection seemed to be associated with about 95% mortality, over 3 to 4 days, among experimentally exposed veligers (Hine et al. 1998). Herpes-like viruses were the main agents that led to high mortalities of the

Pacific oyster *Crassostrea gigas* larvae (Renault et al. 2001). The herpes-like viral infection in larval *Ruditapes philippinarum* was associated with sporadic high mortalities in a commercial hatchery (Renault et al. 2001). Electron microscopic examination revealed the presence of spherical virus-like particles in the digestive gland, kidney, and intestine of moribund scallop *Chlamys farreri* in 2000. The virus was approximately 130–170 nm in diameter and always observed in the cytoplasmic vesicles of infected cells. It was the main cause of the mass mortality of scallops, from July to August since 1997, in the northern area of China (Liu 2002).

With the development of abalone culture industries, the impact of diseases on abalone have become more and more serious. We described, for the first time, the virus infection in abalone *Haliotis diversicolor* Reeve associated with the mass mortalities in Guangdong Province. With respect to the size, morphologic features, and syndrome of the infected abalone, it was similar to the 100 nm diameter spherical virus that was found in the cytoplasm of liver cells of diseased *Haliotis diversicolor* Aqualitis from Fujian Province (Song et al. 2000). In our study, the virus particles were mainly observed in the cytoplasm of the infected cells, but never in the nucleus.

Pathologic changes in infected cells included expanded endoplasmic reticulum and dilated or dissolved mitochondria. In the cytoplasm, the endoplasmic reticulum is associated with the Golgi body and mitochondria and functions in synthesis, transportation, and secretion (Wu Zh 1990). The impact of viruses on cells included the destruction of membrane structures of organelles such as endoplasmic reticulum and mitochondria. The viruses were enveloped by the membrane systems of these organelles (Fig. 2d).

The disease infected all sizes of abalone when the temperature was <20°C. It seemed to break out more easily when the temperature became lower. When the water temperature was at $\geq 23^\circ\text{C}$, mortality did not occur. It is suspected that the viruses propagate only in low temperatures. The optimal temperature for *Haliotis diversicolor* Reeve to grow and develop is about 25°C, and it may be that physiologic changes that occur in the species at lower water temperatures may make the animals more susceptible to infection.

ABSTRACT A new species of *Cryptobia*, was found in the blood of diversicolor abalone, *Haliotis diversicolor* Reeve, derived from farming ponds, on the coast of the south China sea in December 2000. Stained with Giemsa smear, most organisms are spindle-shaped, $12.5 \pm 1.88 \mu\text{m}$ in length, $2.50 \pm 0.85 \mu\text{m}$ in width ($n = 20$), and the nucleus is $1.81 \pm 0.61 \mu\text{m}$ in length, and 1.22 ± 0.33 in width. Two unequal flagella are derived from a flagella pocket. The kinetoplast is mostly single, located anterior to the nucleus. Transmission may be direct, from one host to another through lesions on the skin or gill, or it may be also by a vector.

KEY WORDS: parasite, *Cryptobia* spp, new species, *Haliotis diversicolor* Reeve

INTRODUCTION

Since the early 1990s, epizootic mortalities have been observed in many sea-board farmed discus abalones *Haliotis discus hannai*, and diversicolor abalone, *H. diversicolor* Reeve in China. There are several varied pathogenetic organisms found in cultured abalones, including virus (Li et al. 1998, Nakatsugawa et al. 1998, Wang et al.2000, Fang et al.2002), bacteria (Li et al. 1996, Liu et al.2000, 2001, Lee et al. 2001), parasites (Bower et al. 1989, Gogging & Lester 1995, Ruck & Cook 1998, Ruck & Cook 1999, Chen et al. 2001) and rickettsiae-like organisms (Moore & Robbins 2000, Chen et al. 2001), and the like. A dinoflagellate has been found in blood of pathogenic abalones, *H. diversicolor* Reeve. This study describes the structure of the parasite in farmed abalones on the coast of south China.

MATERIALS AND METHODS

Cultured diversicolor abalones with a mean length of 680 mm (580–720 mm), and mean weight of 20 g, were obtained occasionally from 4 farming ponds in Shanwei, Guangdong Province. After dissection, inhalant lymph blood of abalone was obtained from the

heart and then smeared on to slides. Smears were fixed in methanol for about 5 min, stained with Giemsa's fluid diluted 1:10 with water at pH 7.0–7.2 PBS for about 30 min, then rinsed well in distilled water. Results were observed microscopically.

RESULTS

Most of detected abalones ($n = 20$) were infected by parasites. The parasite density was 2–8 *Cryptobia* sp. in every view ($\times 400$) (Fig. 1 and Fig. 2). The organisms are spindle shaped, $12.5 \pm 1.88 \mu\text{m}$ in length, and $2.5 \pm 0.85 \mu\text{m}$ in width. The nucleus is ellipsoidal with an endosome, situated at 20% to 25% of body length from anterior extremity. The nucleus is $1.81 \pm 0.61 \mu\text{m}$ in length, and $1.22 \pm 0.33 \mu\text{m}$ in width. The kinetoplast is mostly single spherical, located anterior to the nucleus. Two unequal flagella are derived from a flagella pocket. The anterior flagellum, $8.85 \pm 1.23 \mu\text{m}$ in length, is shorter than the posterior one ($15.38 \pm 2.46 \mu\text{m}$). The undulating membrane is not well developed and forms a narrow undulating membrane when stained with Giemsa smear (Fig. 3).

DISCUSSION AND CONCLUSION

The flagellates mostly are pathogenic protozoa that cause disease and mortality in freshwater and seawater hosts. They have been often found in the gills (Lom & Dykova 1992, Diamant

1990), epidermis (Kreier 1977, Kinne 1980), intestinal tract (Kozloff 1948), as well as bloodstream (Chen & Hsieh 1964, Zhao & Ma 1992). A species appearing identical to *Cryptobia helices* has also been reported living in the reproductive organs and intestines of pulmonate land snails in Europe (Leidy 1846). In this investigation a new hemoflagellate (*Cryptobia* sp.) occurred firstly in the blood of abalone. It differs from other described species in its shape and body size, as well as the shape of the nucleus and flagellum (Table 1).

In recent years, Cryptobiosis, caused by the hemoflagellate, has been found in many fishes (Lom & I. Dykova 1992, Kreier 1977, Kinne 1980). The use of monoclonal antibody probes and immuno-chemotherapeutic strategies have been reported to detect the pathogenic hemoflagellate (Lukes et al. 1998, Ardelli & Woo 2001). There are few effective chemotherapies against the parasite in intensive abalone culture facilities. It is, therefore, necessary to develop a sensitive detection technique and an effective control method against this parasitic organism.

ABSTRACT Cell free hemolymph from *Haliotis diversicolor supertexta* was prepared from fluid collected at 1, 4, 8, 12, 24, 48, 96 h after injection with either *Escherichia coli*, *Vibrio parahaemolyticus* or 0.9 NaCl solution (control group). The response of selected innate immune parameters (lysozyme, antibacterial activity, alkaline phosphatase, acid phosphatase, phenoloxidase, and superoxide dismutase) was investigated. Results showed that the activities of ACP (Acid Phosphatase) from abalone injected with *V. parahaemolyticus* were much higher than that of the control group at 24 h after injection. The ALP (Alkaline Phosphatase) activities of abalone challenged with *V. parahaemolyticus* were significantly higher than those of the control group at 8 h and increased further up to 48 h after the challenge. In contrast, the activities of ALP and ACP in the *E. coli*-challenged group showed no statistically significant differences at any of the sampling times. The activities of SOD (Superoxide Dismutase) in cell free hemolymph from the *V. parahaemolyticus*-exposed group were significantly lower than those of the control group at both 1 h and 24 h, whereas there was no difference in SOD activity observed in the group exposed to *E. coli* at any of the sampling times. The activities of lysozyme and phenoloxidase in *Haliotis diversicolor* were relatively low in both control and bacteria-exposed groups when compared with reports for other invertebrates; no significant difference was found between the infected groups and the control for these two parameters, due to the low activities and high individual variance.

KEY WORDS: *Haliotis diversicolor supertexta*, superoxide dismutase, innate immune, acid phosphatase, alkaline phosphatase

INTRODUCTION

Having an open circulation system, abalone has considerable opportunity to encounter the pathogens and pollutants present in its surrounding water. Although little is known about the innate defense system(s) of abalone, some information is available from the study of other molluscs. To cope with the foreign invaders, many bivalves possess cellular and extra cellular defense mechanisms that are remarkably effective. Hemocytes are the main cellular effectors of invertebrate immunity and are capable of recognizing pathogens in a lectin-mediated process (Pipe 1990, Renwratz 1983) and in phagocytosing, thus isolating and inactivating them (for a review see: Canesi et al. 2002). In addition, cell-free hemolymph of certain bivalves has been shown to contain various biologically active substances involved in innate defense, including agglutinins (e.g., lectins), lysosomal enzymes (e.g., acid phosphatase, lysozyme), toxic oxygen intermediates, and various antimicrobial peptides (Canesi et al. 2002).

In abalone, some research has been focused on the cellular defense system. Lebel et al. (1996) have established that two types of hemocytes are present in the blood of the abalone *Haliotis tuberculata*. Moreover, it has also been shown that salinity stress and certain pollutants can affect the migratory and phagocytic activities of these hemocytes (Chen 1996, Martello et al. 2000). Recently, Shelagh et al. (2003) have shown a direct link between stress and the immune reaction in the abalone *H. tuberculata* using immune parameters such as the number of circulating hemocytes, the migratory activity, the phagocytic capacity, and the respiratory burst responses of the hemocytes.

H. diversicolor supertexta is one of the most commercially important cultured abalone in southern China. However, although

progress in abalone culture has occurred in recent years, abalone culture remains an expensive undertaking, due in part to the catastrophic effects of frequent infectious disease outbreaks (Zhang et al. 2001). To understand the mechanism of innate immunity by which *H. diversicolor supertexta* defends itself against pathogens, we infected *H. diversicolor supertexta* with a nonpathogenic bacterium (*Escherichia coli*) as well as a pathogenic bacterium (*Vibrio parahaemolyticus*) and compared several immunity-related parameters at different exposure times.

MATERIALS AND METHODS

Animals, Immune Challenge, and Hemolymph Collection

Abalone (*Haliotis diversicolor supertexta*) were collected from a commercial farm (Futian, Dongshan, Fujian Province) and maintained in polyethylene tanks, each containing 20 animals in 50 L of aerated and sand-filtered seawater at 23°C to 25°C. Animals were left undisturbed for 2 wk to acclimate to their environment. Abalone were challenged by injecting either 50 L of *Vibrio parahaemolyticus* (isolated from diseased abalone, Zhang et al. 2001) in 0.9% NaCl (6.7×10^7 cells/mL), 50 L of *E. coli* in 0.9% NaCl (6.7×10^7 cells/mL) or 50 L of 0.9% NaCl (as control) into their pleopod muscle. After injection, the abalone were returned to their original tanks containing seawater at the same temperature. Hemolymph (approximately 1.0 mL/animal) from unchallenged or challenged abalone was collected at 1, 4, 8, 12, 24, 48, 96 or 192 h post challenge using a capillary to withdraw fluid from a center incision in the pleopod muscle. Samples were collected into a 1.5 mL centrifugal tube and immediately centrifuged at 150g for 5 min at 4°C to remove hemocytes. Cell-free hemolymph (CFH) samples were frozen at -80°C until used.

Biochemical Assays

ACP and ALP activity assays were carried out according to King's method (Cui 1981) using a commercial kit (Nanjing

*Corresponding author. E-mail: zhangziping@hotmail.com

Jiancheng Bioengineer research institute, China). Analysis was performed in 96-well flat-bottomed microtitre plates and the concentrations of products were monitored spectrophotometrically at 550 nm after incubation of the plate at 37°C for 30 min in the case of ACP, or for 20 min at 37°C for ALP. The activity of ACP and ALP was defined as the amount of phenol (mol) produced under the mentioned conditions per mg protein.

SOD activity assay, a modification of the xanthine-xanthine oxidase assay (McCord & Fridovich 1969) was adapted by using a kit (Nanjing Jiancheng Bioengineer Research Institute, China). The assay was carried out in 96-well flat-bottomed microtitre plates and 1 nitrite unit (NU) of SOD was defined as the quantity of enzyme (per mg protein) that inhibits the reduction of cytochrome c by 50%.

Phenoloxidase activity was measured according to the methods of Horowitz (1952) and Ashida (1971) with L-Dopa used as the substrate. Briefly, 20 µL of cell-free hemolymph samples were added to the wells of a 96-well flat-bottomed microtitre plate in triplicate. To each well, 200 µL of PBS (0.1 mol/L, pH = 6) and 20 µL of L-Dopa solution (0.01 mol/L), were added and the absorbance was read continuously at 490 nm for 15 min. One unit (PO activity) was defined as absorbance change in 490 nm of 0.001 in 1 min and the concentration was expressed as units of activity per mg of protein contained in the sample.

Lysozyme activity was analyzed according to Wilson and Ratcliffe (2000). Briefly, purified lysozyme (100,000 units/mg; Sigma) was diluted in PBS pH 6.2 to give the standards of 0, 2, 4, 8, 12, 16, 20, and 30 g/mL. Aliquots (10 L) of each standard, or the CFH samples were added to the wells of a 96-well flat-bottomed microtitre plate in triplicate. To each well, 250 L of a suspension of lyophilized *Micrococcus luteus* in PBS (0.3 mg/mL; Sigma) was added and the absorbance was continuously monitored at 450 nm for 10 min. For the calculation of lysozyme-like activity, the values for the standards were plotted on a graph of $DA_{450\text{ nm}}/10\text{ min}$ against lysozyme activity (1 unit-change in $A_{450\text{ nm}}$ of 1.0 in 1 min). The values for lysozyme-like activity for each cell-free hemolymph sample were extrapolated from this graph and the concentration was expressed as units of activity per mg protein contained in the sample.

Total protein content of each cell-free hemolymph sample was determined according to Bradford (1976) using bovine serum albumin (BSA) as a standard.

Statistical Analyses

All data are presented as means and standard errors of at least 20 specimens. For comparison of two means, paired or unpaired Student *t*-tests were used where appropriate. $P < 0.05$ was considered as the lower limit of significance, whereas $P < 0.01$ was considered as the most significant difference.

RESULTS

Time Course of ALP and ACP Activities in Cell Free Hemolymph Following Bacterial Challenge

The activities of ACP from abalone injected with *V. parahaemolyticus* were significantly higher than that of control group at 24 h after injection (Fig. 1). In contrast, the activities of ACP between *E. coli* group and control group demonstrated no signifi-

Figure 1. Time course of ACP activities in cell free hemolymph following bacterial challenge. All data are presented as mean and standard errors of a minimum of 20 abalone. * = significant ($P < 0.05$) differences from values of control group (0.9% NaCl injection). All abalone had died at 192 h after injection and no data were available at that time.

cant difference at each sampling time (Fig. 1). All abalone died at 192 h after injection and no data were available at that time.

The ALP activities of abalone injected with *V. parahaemolyticus* were significantly higher than that of control group at 8 h ($P < 0.05$) and were even more significant at 48 h ($P < 0.01$). Interestingly, at 96 h post exposure the ALP activities of the *V. parahaemolyticus*-challenged group were notably lower than that of control and *E. coli* group (Fig. 2). Same as ACP, the activities of ALP between *E. coli* group and control group demonstrated no significant difference at each sampling time (Fig. 2).

Time Course of SOD Activities in Cell Free Hemolymph Following Bacterial Challenge

The activities of SOD in cell free hemolymph from *V. parahaemolyticus* group were significantly lower than that of control group at 1 h and 24 h. However, there was no statistical difference between the *E. coli*-challenged group and control group at any

Figure 2. Time course of ALP activities in cell free hemolymph following bacterial challenge. All data are presented as mean and standard errors of a minimum of 20 abalone. * = significant ($P < 0.05$) differences from values of control group (0.9% NaCl injection), ** = the most significant ($P < 0.01$) differences. All abalone had died at 192 h after injection and no data were available at that time.

Figure 3. Time course of SOD activity in cell-free hemolymph following bacterial challenge. All data are presented as mean and standard errors of a minimum of 20 abalone. * = significant ($P < 0.05$) differences from values of control group (0.9% NaCl injection), ** = the most significant ($P < 0.01$) differences. All abalone had died at 192 h after injection and no data were available at that time.

sampling time when the activities of SOD were considered (Fig. 3). Moreover, as a general trend, the average of the SOD activity from the *V. parahaemolyticus* group was lower than that of control and *E. coli* group at each sampling time.

Time Course of Lysozyme Activities in Cell Free Hemolymph Following Bacterial Challenge

No significant differences in the activities of lysozyme were observed under any of the exposure conditions and at any of the times of exposure. The degree of variation, in the cell-free hemolymph samples between individual abalones was, however, quite large (e.g., 24 h after injection with 0.9% NaCl, the samples ranged from 0.015–0.472 U/mg) and any underlying trend may have been masked by this extreme variability (Fig. 4).

Time Course of Phenoloxidase Activities in Cell Free Hemolymph Following Bacterial Challenge

The activities of phenoloxidase in *Haliotis diversicolor supertexta* were low (Fig. 5), considerably lower than that reported in

Figure 4. Time course of lysozyme activities in cell free hemolymph following bacterial challenge. All data are presented as mean and standard errors of a minimum of 20 abalones. All abalone in *V. parahaemolyticus* group died at 192 h after injection and no data were available at that time.

Figure 5. Time course of phenoloxidase activities in abalone following bacterial challenge. All data are presented as mean and standard errors of a minimum of 20 abalone. All abalone had died at 192 h after injection and no data were available at that time.

other invertebrates. For example, values of 2.41–3.46 have been reported in scallop *Chalymys ferveri* (Sun & Li 1999). No significant differences were observed under any of the exposure conditions and at any of the times of exposure.

DISCUSSION

A series of immune defense reactions will normally be elicited if bacteria or other pathogenic microbes enter the body of an invertebrate (Cheng 1978). Because invertebrates do not have the capacity to mount humoral and adaptive immune responses, hemocytes play an important part in the shellfish defense system because of their ability to phagocyte, encapsulate, and kill microbes (Zhou & Pan 1997). In addition, processes such as agglutinins, lysosomal enzymes, and toxic reactive oxygen intermediates form during a respiratory burst and may also play an essential role in innate immune responses to clean invading pathogens from the shellfish tissue and hemolymph (Aswanik et al. 1999, Mitta & Vandembuleke 1999, 2000).

ACP is an important component of the phagocytic lysosome, and is released during the process of phagocytosis and encapsulation (Zhai et al. 1998). Mollusc ACP is found mainly in granulocytes and is responsible for lysis and eventual decomposition of foreign agents including many bacteria. It has previously been shown that the concentrations of lysosome enzymes in some shellfish were increased after they were infected by bacteria (Cheng 1979). In the present study, the activities of ACP and ALP in *V. parahaemolyticus* group were significantly increased at the time points before 24 h and 48 h of the exposure respectively.

These results indicated that *V. parahaemolyticus* induced the ACP and ALP activities and activated the immune defense response in abalone, *Haliotis diversicolor supertexta*. However, the *E. coli* had no effects on ACP and ALP activity in our study, because we observed no significant differences to results obtained from the control group. Our results are in contrast to those reported by Sun and Li (1999) who observed that *E. coli* can also significantly induce ACP and ALP activities in the scallop, *Chalymys ferveri*.

It has been previously suggested by Feng (1988) that the elevation of lysosome enzyme (including lysozyme, ACP and ALP)

activity was not only one mechanism of immune defense, but that its depletion may also be a symptom of disease. In the present study, ALP activities declined noticeably at 96 h and ACP activity was substantially decreased at 48 h post injection when the abalone were exposed to *V. parahaemolyticus*. Thus, it may be suggested that the capability of the immune defense in abalone can be disturbed by this pathogenic bacterium and may further be an indicator of the severity of infection in this animal. It was noteworthy that we found some evidence of pathologic changes in abalone injected with *V. parahaemolyticus* (data not shown). Symptoms of the diseased abalone included increased mucus, decreased activity, and loss of absorbability. Furthermore, no samples were available at 192 h after injection due to the high mortality in the *V. parahaemolyticus* injected group (no mortality was observed in either the control or *E. coli* exposed group).

Superoxide dismutase is capable of eliminating superoxide free radicals and may prove protective in bivalves, freeing them from the impact of reactive oxygen species (Nasci et al. 2002). In general, SOD will be induced when the amount of free radical increased. The activities of SOD in cell free hemolymph from the *V. parahaemolyticus*-challenged group were significantly lower than that of the control group at 1 h and 24 h in the present study. Our results are in agreement with the previously reported results of Ding et al. (1996), who infected *Haliotis discus hama* with *E. coli* or *Vibrio* spp. and found that the SOD activity in cell-free hemolymph was markedly depleted. These phenomena are so called negative-induced, which may also be an indication of immune defense activation in abalone. The reducing of SOD activities allows the relative long existence of reactive oxygen intermediates and is helpful against bacteria. Again, as was observed for the ALP and ACP responses, there was no significant difference between the *E. coli*-treated group and the control when SOD in cell-free hemolymph was considered. These results may indicate that abalone immune defense shows different responses to patho-

genic and nonpathogenic bacteria, although the mechanism by which they might be capable of distinguishing such differences remains unclear (*V. parahaemolyticus* is a conditional pathogenic bacterium, it caused abalone disease under our experiment condition. *E. coli*, in general, is a natural bacterium and had no effects on abalone in our study).

The activities of lysozyme, and phenoloxidase in *Haliotis diversicolor supertexta* were low. For example, lysozyme activity of $4. \pm 0.6$ units/mg protein was recorded in cell-free hemolymph of *Blaberus discoidalis* (Wilson & Ratcliffe 2000). While in abalone, *Haliotis diversicolor supertexta*, the mean value was 0.2 units/mg protein below. As mentioned in Results, the activities of phenoloxidase in *Haliotis diversicolor supertexta* were 10 times lower than in the scallop *Chalymys ferveri* (Sun & Li 1999). Therefore, it may be that these two parameters may play a less important role in immune defense in abalone. High variability was observed between individual samples.

Further work is required to ascertain the role of these enzymes in abalone immune defense. Fortunately our research group has cloned the SOD gene in abalone, *Haliotis diversicolor supertexta*, and further research to determine why and how the SOD activity is diminished, following challenge by such pathogenic bacteria, is ongoing. Genomic scale investigation is also being carried out in our laboratory on the molecular mechanism of abalone response to pathogenic and non-pathogenic bacteria by using a combination of cDNA microarray and other technology.

THE ECOLOGY OF POLYCHAETES THAT INFEST ABALONE SHELLS IN VICTORIA, AUSTRALIA

H. MCDIARMID,¹ R. DAY,^{1*} AND R. WILSON²

¹Zoology Department, University of Melbourne, Victoria, 3052, Australia; ²Museum of Victoria, Carlton Gardens, Victoria, 3051, Australia

ABSTRACT Very little is understood regarding polychaete borers and the effect they have on their hosts. In Victoria and elsewhere in Australia many stunted populations of *Haliotis rubra* have extensively bored shells. This study investigated the infestation by polychaetes of abalone shells and their effect on the health and growth of abalone. Polychaete numbers were estimated by providing diatom food so that they emerged. Borers were most prevalent in the spire region and near closed respiratory pores. In larger *H. rubra* shells, the frequency of polychaete borers increased and borers were present in more parts of the shell. Experiments showed that uninfested *H. rubra* and *H. laevigata* shells from a hatchery could be colonized by *Polydora woodwicksi* and *Dipolydora armata* from infested abalone over short periods in the laboratory. Live specimens of *P. woodwicksi* were observed for the first time. Larger shells of *H. rubra* were found to be more susceptible to polydorid infestation than large *H. laevigata* or small *H. rubra*, apparently because they provide more suitable sites for settling larvae. Larvae from both species colonized specific places on abalone shells. X-ray photographs were used to determine burrow shapes of *Boccardiella* MoV 3840, *Polydora woodwicksi*, and *Dipolydora armata*, which have not been previously described. *Boccardiella* MoV 3840 was found to cause the host abalone to form mud blisters. Rates of burrow growth could be determined using sequential x-rays. High levels of boring were correlated with shell thickness and had a detrimental effect on several condition indices of host abalone, showing that borers have marked detrimental effects on the health and growth of abalone. Thus borers may severely affect fishery yield and productivity.

KEY WORDS: parasite-host interaction, host susceptibility, shell parasites, polydoridae, burrow morphology, burrow growth, abalone productivity

INTRODUCTION

Blacklip abalone *Haliotis rubra* (Leach) are the most abundant abalone species in Victoria and are the basis for a lucrative fishing industry, worth over \$58 million a year in Victoria in 1999 to 2000 (ABARE 2001). This species is also important to the rapidly developing Victorian abalone aquaculture industry. *H. rubra* are known to host a variety of organisms that bore through their shells (Shepherd & Breen 1992). Greenlip abalone (*H. laevigata*, Donovan), which support important commercial fisheries elsewhere in Australia, appear to be less often affected. The major species responsible for this boring belong to the family Spionidae (Annelida: Polychaeta) (Blake & Evans 1973). These polychaete borers, known as polydorids, may have important consequences for the biology of the hosts, and thus for the economics of the fishery and mariculture. At this stage however, there is little hard data to assess these claims.

Most research on shell borers is either taxonomically based or ecologically based. Taxonomic studies often concentrate on one species of boring organism and regularly do not record the host species or the effect on the host. Ecologic studies frequently seem to provide inaccurate descriptions and records of the species of boring organisms present (e.g., Smyth 1990). In either case, information is lost.

Polydorids produce eggs in capsules attached to the burrow, often in strings, and the larvae usually hatch at the 3 setiger stage and develop in the plankton before settlement, but some species are lecithotrophic (Blake & Woodwick 1975, Woodwick 1977, Day & Blake 1979, Sato-Okoshi et al. 1990). The settlement and burrowing behavior of polydorids is poorly understood considering their prevalence in easily studied tidal and subtidal environments and their significance to commercial fisheries (Blake 1996). Blake (p. 85) stated "we know little about how species initially

become established in such a habitat (mollusc shells), the mechanism by which they expand their burrow, how they feed and how they interact with their hosts."

The impact of borers on commercially important bivalves depends on the site of colonization of the host shell (Blake & Kudenov 1978). Preferences for mollusc hosts and the effects of host size or encrusting algae on colonization by borers are also not currently understood. To understand the relationship between polydorids and abalone, one needs to determine how they become established in a shell, and the factors affecting establishment.

Burrowing by polydorids was initially believed to be carried out mechanically by the chaetae, in particular the modified chaetae of the fifth chaetiger (Blake & Evans 1973). The most recent evidence however, suggests chemical breakdown of the shell instead of a mechanical process (Haigler 1969, Zottoli & Carriker 1974, Sato-Okoshi 1997). The burrows are not often seen to penetrate the inner surface of their host's shell and do not have any direct contact with the host animal, but this seems to be because the burrowing activity induces the host to secrete a protective layer of dark conchiolin, followed by a nacreous shell layer, on the inside of the shell (Haigler 1969, Kent 1979, Blake 1996, Marshall & Day 2001). High levels of burrowing cause some molluscs, including abalone, to significantly increase the shell thickness (Marshall & Day 2001). This repair response, of the mollusk, to holes penetrating the shell takes considerable time to complete (Thomas & Day 1995) and has been suggested to affect the health of the animal and even slow its growth (Kent 1979, Kojima & Imajima 1982, Handley & Berquist 1997, Handley 1998).

The burrows end at two exterior apertures from which the worm feeds (Blake 1996). The boring activities of polydorids result in simple U-shaped burrows, Y-shaped burrows, pear-shaped, complex branching burrows, shallow depressions, or mud blisters (Blake & Evans 1973, Blake 1996). Burrow shape and size is also believed to be a factor in the effect of the borers on the host mollusc (Blake & Evans 1973, Zottoli & Carriker 1974). The rate

*Corresponding author. E-mail: r.day@unimelb.edu.au

of boring of different species may also determine the effect on the host mollusc (Zottoli & Carriker 1974).

There is little known about infestation of abalone (*Haliotis* spp.) by polydorids. A preliminary study (McDiarmid & Wilson, unpublished data) has identified several polydorid species in abalone that do not match any species known for Australia. This, and their presence only near major shipping ports, suggests some may be introduced as "exotic" species. Further taxonomic work is required to establish whether this is the case. The effect on the abalone is believed to increase with the degree of infestation (Blake & Evans 1973, Kojima & Imajima 1982). Abalone with shells weakened by many burrows would provide easier prey for large predators such as fish, stingrays, and octopus (Shepherd & Breen 1992).

This study examines the host-parasite relationship between boring polydorids and *H. rubra* and *H. laevigata*, in particular the effect of infestation on *H. rubra*. New methods are described that can be used to examine colonization behavior and the growth and morphology of the burrows formed and to measure the effect on the host.

MATERIALS AND METHODS

Extraction and Identification

Polychaetes were extracted from abalone shells by placing them in a 50% alcohol, 50% seawater mix. This method caused the worms to either escape their burrows completely and then die where they could be easily collected, or at least expose themselves out of their burrows where they could be extracted manually. An interactive key was constructed (Wilson & McDiarmid 2004), and used in conjunction with a review of the spionids present in southern Australia by Blake & Kudenov (1978) to identify the key features of these taxa.

Pattern of Infestation of Abalone Shells

Seventy abalone of varying sizes collected from Point Cook reef were used to determine whether the area of the shell and/or the level of encrusting algal cover were correlated with the number of polydorids present in the shell. The number of polydorids was determined by placing abalone shells in fresh seawater, to which dead diatoms were added to encourage the feeding behavior of the worms, and observing them under a stereo microscope. Polydorids are easily observed even to the naked eye when they are feeding, because their palps are distinctive (Fig. 1).

Figure 1. Photograph of the spire of a shell of a blacklip abalone (*Haliotis rubra*), showing two pairs of feeding palps of polydorid polychaetes (*Polydora woodwicki*) protruding from burrows that extend as mucus tubes above the shell surface. The worms were induced to protrude by mixing dead diatoms into the water.

To determine the pattern of infestation over the shell, shells were divided into three sections: the spire, the area between the ostia and columella and the flat section of the body whorl between the spire and the growing margin (Fig. 2). Each section was observed for a period of 5 min. Counts on every fifth abalone were repeated and the standard deviation of counts was found to be very low ($SD = 2.77$). Algal cover was graded using a scale devised by Smyth (1989). Areas of shells and sections of shells were determined by wrapping the shells in graph paper and counting squares.

The polychaetes were extracted from 15 juvenile (30–60 mm) and 15 adult (>80 mm length) *H. rubra* and identified, to determine any host preferences of the polydorid species.

Colonization of Abalone Shells by Polydorids

Haliotis rubra infested with borers were collected from a depth of 3–4 m off the south eastern boundary of the Point Cook Marine Park in Port Phillip Bay, or at "Fred's Wall," 50 m offshore from the breakwater at Williamstown beach. Several shells from each sample of abalone were set aside and the worms were extracted for identification. One hundred and eighty juveniles of *H. rubra* and *H. laevigata* Donovan, free from borers, were purchased from an abalone mariculture facility for the colonization experiment. All abalone were wrapped in damp towels and placed in cool boxes during transport and left for 1 wk in the aquarium system to acclimatize before experiments. Injured or dying animals were eliminated.

To investigate the colonization behavior of borers and the susceptibility of abalone species to colonization by polydorid larvae, "recipient" hatchery abalone without borers were placed in contact with infested wild abalone from Point Cook reef ("source" abalone) carrying a known number of polychaetes. Recipient abalone were all checked to make sure no boring polydorids were present. They were then placed in either direct or indirect contact with infested abalone, using tanks either containing infested abalone or receiving water from a tank containing an infested source abalone. This experiment was conducted in tanks provided with flowing

Figure 2. Diagram of an abalone shell, indicating the shell areas used to count polydorids on 70 abalone shells, to determine patterns of infestation in different sized abalone. These areas are: the spire; the area between the ostia and the columella; and the flat section of the body whorl of the shell.

seawater from a large cooled recirculating seawater system, with temperature ranging from 11 C to 15 C.

Eighteen abalone with 30 to 40 polydorids present in the shell were used as source abalone in the "direct" colonization treatments. Three abalone that had ~180–220 polydorids were selected to be used as source abalone in the "indirect" colonization treatments. Several shells from the same sample were set aside and the polychaetes were extracted for identification.

In each of the 9 direct colonization replicates for *H. rubra* and *H. laevigata*, two (30–35 mm) juvenile and one (60–65 mm) subadult abalone were used as recipients and were placed in 20-L polypropylene buckets along with an infested abalone (Fig. 3). In the indirect colonization experiment, water from a tank with the heavily infested abalone was led into 6 jars (6 L) containing 3 recipient abalone (one ~60 mm and two ~30 mm). Three jars contained *H. rubra* recipients, and three contained *H. laevigata*. There were three blocks of this arrangement (Fig. 4). Nine 20-L buckets containing *H. rubra* and nine containing *H. laevigata* were used as controls in a similar set up to the direct colonization treatment, without infested abalone. The replicates for each treatment and control were randomly placed, and assigned to alternating water supply outlets to reduce effects due to water flow rate.

The experiment was carried out in constant darkness, because this is believed to induce reproduction of the polychaetes (Evans 1969) and also seems to reduce stress on the abalone (previous observations). The tanks were cleaned every 4 days and fed artificial abalone food every 2 days. If an infested source abalone died it was replaced with another one carrying a similar number of polydorids. After 72 days shells from each of the treatments were closely examined under a dissecting microscope and the number of polydorids and the locations of their burrows were recorded. The polydorids were then removed for identification.

Figure 3. Diagram showing the arrangement of abalone in each of 9 replicates of the "direct" colonization experiment for both *Haliotis rubra* and *H. laevigata*. One large infested abalone (~30 worms) was placed alongside one medium sized (~60mm) and two small (~30mm) uninfested abalone. In controls the infested abalone was omitted.

Figure 4. Diagram showing the arrangement of abalone in each of the 3 blocks of the "indirect" colonization experiment. As indicated by arrows, water flowed from the tank with an infested abalone into 6 jars containing uninfested recipient abalone of the same sizes as in Figure 3. Three jars contained *Haliotis rubra* and 3 contained *H. laevigata*.

Burrow Morphology and Growth Rate

To determine the morphology and rate of expansion of the burrows, abalone shells with live polychaete borers from the wild and from the colonization experiment were x-rayed at the end of the colonization experiment and again 29 days later. Both adult and juvenile polychaete borers were investigated. X-rays were taken using a Hewlett Packard Faxitron x-ray system. An exposure of 30 Kv, 0.2 mA for 12 sec was used. After the last x-ray was taken the polychaetes were removed from the shell to relate the burrow morphology to the species producing it. Burrow areas were determined by tracing them onto graph paper, and the percentage increase between x-rays in the overall size of the burrow was calculated.

Effects on Host Abalone

To relate the condition of abalone to the abundance of borers in their shell, 65 *H. rubra* from Williamstown of a size range 95–110 mm were haphazardly selected. Each abalone's length and width was measured and the percentage of the shell bored was estimated using a grading system adapted from Handley (1997, 1998) (Table 1). Repetitive tests were carried out on 20 of the shells to determine the precision of this method. Eighty percent of these tests

TABLE 1.

The definitions of the grades used to describe bored abalone shells.

Grade	Percentage of Shell Bored
1	0% to 10%
2	10% to 30%
3	30% to 60%
4	60% to 80%
5	80% to 100%

produced the same grade and the remaining ones were within one grade of the original.

The abalone body was removed from the shell and placed on absorbent paper to remove excess water, to determine the body wet weight. Wet muscle weight was recorded after the head and viscera were removed. Dry muscle weight was obtained by placing it in a drying oven at 60°C for 48 h or until a constant weight was achieved (Davenport & Chen 1987, Roper et al. 1991, Handley 1998).

The thickness of the shell was measured using modified vernier calipers at the top of the spire. Abalone are known to thicken the shell in response to borers (Marshall & Day 2001) and the extra shell deposition presumably diverts resources from other tissues (Blake & Evans 1973, Shepherd & Breen 1992). Because the abalone were collected just after the spawning season, the effect of boring on reproductive condition could not be determined.

Three indices were used to measure the condition of the abalone:

- Wet weight of muscle divided by the wet animal weight (CI_{Wet}). Healthy animals would present a higher ratio because the muscle tissue is used to store glycogen as an energy reserve (Carefoot et al. 1993). Note that the gonads of all abalone were spent.
- Dry muscle weight divided by wet muscle weight (CI_{Dry}). This index determines the amount of water in the muscle. Healthier muscles have a lower water content (Carefoot et al. 1993, Handley 1998).
- The width divided by the length of the shell (CI_{WL}). Faster growing abalone (and thus presumably healthier) are known to lengthen the shell more in comparison to the shell width (Oakes & Fields 1996, Worthington et al. 1995).

RESULTS

Pattern of Infestation of Abalone Shells

There was a significant correlation between the shell area and the number of polychaete borers in the shell ($r = 0.698$, $P < 0.001$), but a linear regression explained only about half of the variation in the data ($R^2 = 0.478$) (Fig. 5). The deviations of the data from the line suggest that shells below about 1800 mm² (22 mm length) are seldom infested, and that the number of borers may increase more rapidly with size in larger shells. When the

Figure 5. Scatterplot of the number of polydorids present in 70 abalone shells against shell area. The correlation coefficient was 0.698, but the fitted linear regression shown explains only about half (0.449) of the variation in polydorid numbers.

residuals for the number of borers versus shell area were plotted against the grades of encrusting algal cover, there was no obvious relationship. This may be because encrusting algal cover was correlated with shell area ($r = 0.746$).

Table 2 shows the species of polychaete borers present on different sized abalone. Only 4 species were found in abalone <60 mm length, and *Dodecacaria* sp., which was present in 83% of large shells, was absent in these smaller shells. Only the spire area was infested (usually in the groove between the whorls) in smaller shells (30–50 mm), while in progressively larger abalone increasing proportions were infested around the closed ostia and the columella (Fig. 6). Only abalone >100 mm were commonly infested in the flat section of the body whorl. Many borers in the flat section were observed near spirorbid or other serpulid polychaete tubes attached to the shell surface.

Colonization of Abalone Shells by Polydorids

None of the abalone in controls and none of the smaller juveniles (30–35 mm) in other treatments became infested. The presence/absence of infesting polydorids in the subadult abalone (60–65 mm) was analyzed (Table 3). Note that the use of these data avoids the assumption that each polydorid larva colonized the abalone independently.

H. rubra was found to be significantly more susceptible to infestation by borers than *H. laevigata* ($\chi^2 = 4.96$, $df = 2$, $P < 0.05$). The infested *H. rubra* were also each colonized by more polychaetes than infested *H. laevigata*, so that the total number of polychaetes present in all shells was greater in *H. rubra* (Fig. 7). The proportion of *H. rubra* and *H. laevigata* infested with polydorids was not significantly different in the "direct" and "indirect" treatments ($\chi^2 = 1.56$, $df = 1$, $P = 0.3$, combined test for both hosts). This result should be regarded with caution because the numbers of shells infested are small in this experiment, but it is

clear that polydorid larvae can be carried in the water to infest new hosts.

The number of borers in each section of the shell expected by chance, based on the relative area of each section, was calculated. For each abalone species the observed numbers differed significantly from those expected (*H. rubra*: $\chi^2 = 150.4$, $df = 3$, $P < 0.001$, *H. laevigata*: $\chi^2 = 26.2$, $df = 3$, $P < 0.001$). The pattern of infestation did not differ significantly between the two abalone species ($\chi^2 = 4.259$, $df = 4$, $P > 0.05$) (Fig. 8). These results should be viewed with caution however, due to the low numbers for *H. laevigata* and the fact that this analysis assumes each spionid larva colonized independently. In summary *H. rubra* are more susceptible than *H. laevigata* and borers are more common than expected in the spire, closed ostia and below the small calcareous tubes of polychaetes attached on top of the abalone shells.

Two species of spionid polychaetes, *Polydora woodwicki* (Woodwick) and *Dipolydora armata* (Langerhans), infested the abalone in this experiment. Several larvae of polydorids were observed crawling over the surface of juvenile abalone shells until they found a suitable crevice. These larvae were then observed to begin burrowing at these sites, but subsequent observations after a short period of time often showed they were no longer present, leaving the burrow half started. Those that did stay and produce large burrows were found to be *P. woodwicki*. *Dipolydora armata*

burrows were much smaller and larvae of this species were not observed.

Burrow Morphology and Growth Rate

During this experiment it was observed that the majority of polychaetes present in a shell survived the death of the abalone. Their survival depended on the shell staying upright and being placed in an area of water flow and available food. The ability of the polychaetes to survive in an empty shell for a period of time allowed X-rays to be taken. Further, they did not bore through the inner surface of the shell during the 46 days that the dead shells were held.

Because several of the worms died after the first x-ray, presumably due to the stress of the transport involved, the expansion

of only 3 burrows was observed over the 29 days between x-rays (Fig. 9). Two of the burrows were formed by *Polydora woodwicki* and increased their sizes by 18.9% and 27.6% respectively, the third burrow was formed by *Dipolydora armata* and increased its size by 15.9% over the 29 days.

The shape of the burrow can be seen clearly in several of the x-rays; and burrows from the two species were found to be very distinctive. *Dipolydora armata* exhibited extensive and intricate burrows, whereas *P. woodwicki* had a distinct U-shaped burrow. The U-shape of burrows for *Boccardiella* MoV 3840 (sp. nov.) are also clearly visible in Figure 10A, and over the entire abalone shell in Figure 10B. This species was found only in abalone from Mallacoota. Note that these burrows do not interconnect, and change direction just before crossing another burrow. They are distinctive and clearly different to burrows of *P. woodwicki*. A mud blister, in

The burrow increased in size by 18.9%. c to d. Burrow size increased by 15.7%. e to f. Burrow formed by *D. armata* at end of colonization experiment (72 days) and 29 days later. Burrow size increased by 27.6%.

Figure 10. X-rays of abalone shells from Mallacoota showing the difference between heavily bored and lightly bored shells. A. Lightly bored abalone shell, with a few burrows of *Boccardiella* MoV 3840 (1). Tubes on the shell surface formed by serpulid worm are also visible (2). B. Heavily infested abalone shell with burrows through the entire shell, formed by *Dipolydora armata* (1), and by *Boccardiella* MoV 3840 (2). A mud blister formed by *Boccardiella* MoV 3840 beneath the columella area of the shell is shown at (3).

which the abalone has walled off a space inside the shell with a new shell layer, is also shown in Figure 10B, and in cross-section in Figure 11. All blisters were found to be full of sediment and *Boccardiella* MoV 3840. Thus, X-rays (Figs. 9, 10B) can be used to identify burrows made by *P. woodwicki* and *Boccardiella* MoV 3840 and the smaller intricate burrows formed by *Dipolydora armata* and also reveal mud blisters, as well as the extent to which borers have colonized a shell.

Effects on Host Abalone

Many heavily bored shells were brittle and were shattered during the process of removing the abalone soft tissues, so that shell parameters could not be recorded. A Pearson correlation matrix of all the indices measured showed they were not correlated with each other or the spire thickness, so that they represent independent measures of condition. Both wet muscle weight as a proportion of body wet weight and the ratio of dry to wet muscle weight decreased significantly as the extent of boring increased ($F = 16.604$; $df = 1, 58$; $P < 0.001$ and $F = 7.655$; $df = 1, 58$; $P =$

Figure 11. The edge and columella of a blacklip abalone shell from Mallecoota. There is evidence of heavy boring in the outer shell (1). The abalone has formed a mud blister by laying an extra layer of shell inside the normal shell surface (2). The compartment (3) formed by the abalone is filled with sediment and polydorids. The polydorid responsible does not match any currently described species from Australia (*Boccardiella* MoV 3840).

0.008 respectively). The width to length ratio increased significantly with increased boring ($F = 4.638$; $df = 1, 58$; $P = 0.035$). We did not find good evidence that the thickness of the shell at the spire increased with more extensive boring ($F = 1.402$; $df = 1, 31$; $P = 0.245$), perhaps because spire thickness would relate specifically to boring beneath the spire. Boring changed shell shape in other ways (Fig. 12). The inner surface is greatly deformed, and the overall shape of the shell is also affected in heavily bored abalone: it is wider than the lightly bored shell and the columella shelf is enlarged.

DISCUSSION

Pattern of Infestation of Abalone Shells

The positive relationship between the size of the shell and the number of borers found in this study has also been observed in the abalone *Haliotis diversicolor* Reeve (Kojima & Imajima 1982), and in other molluscs (Mohammad 1972). We also found that the diversity of borers increased with host size. Both relationships would follow from the longer exposure to borers of older shells, and the fact that a larger shell area would provide a larger target for planktonic larvae to encounter and allow more borers to burrow. Adult abalone do not hide in crevices as juvenile abalone do, and thus would experience more water flow. They may also encounter more settling borers. Shell structure may also influence the degree of boring, as adult abalone shells are eroded, particularly at the spire. It is possible that the outer layer of prismatic calcite is more resistant to borers (Thomas & Day 1995), so that boring increases once it has worn away on the older spire area. Note that the closed

ostia are plugged with aragonite nacre, and this is another area where borers are common.

The larger number of species in larger shells may also be due to some being secondary borers. *Dodecaceria* sp., which was present only in large shells, requires previous boring to be present in the shell (Gibson 1978). Such secondary borers recolonize unused burrows and extend these burrows for their own use (Smyth 1990).

Species common on smaller shells are likely to be primary colonizers. Identifying the primary borers is important, because preventing boring by these species would prevent the establishment of other borers. The colonization experiment reported here definitively identifies *Dipolydora armata* and *Polydora woodwicki* as primary colonizers, and as having planktonic larvae. Both were common on small abalone. Several species found on juvenile shells were not much more common in adult shells. These species may be suppressed by other borers, or the epibiota on larger shells.

Colonization in the Laboratory

Polydora woodwicki and *Dipolydora armata* were found to easily reproduce in tanks, and thus may affect aquaculture farm productivity and economic performance. Their planktonic larvae appear to settle in short periods, and could spread easily in mariculture facilities.

The laboratory experiments were designed to examine colonization while eliminating confounding influences in field observations. Our observations of the larval behavior of *P. woodwicki*, and the fact that *Haliotis rubra* were more susceptible than *H. laevigata* to colonization, suggests that small crevices associated with shell sculpture facilitate colonization by this polydorid. Shells of *H. rubra* are more sculptured than those of *H. laevigata*, and the spire and ostia are much more pronounced. Further, few borers were found in the flat parts of the shell, and these were often beside the tubes of spirorbids on the shell. Nothing was known about the colonization behavior of *P. woodwicki* prior to this study, but Zottoli & Carrier (1974) found that *Polydora websteri* (Hartman) preferred shell crevices on the oyster *Crassostrea virginica* and the mussel *Mytilus edulis* Lamarek. Blake (1996) suggested crevices provided the juvenile with a place to form a simple tube, to anchor itself and then initiate a burrow.

The observations of *P. woodwicki* larvae colonizing are the first observations of this type for this species. Borers that left burrows

Figure 12. Effect of extensive boring on the size and shapes of abalone shells. a. Top view. b. Bottom view with animal removed. c. Side view. Extensively bored shell on the right in (a) and on the left in (b) and (c).

unfinished may have either died or left the burrow deliberately. The larvae may begin to burrow at one site on the surface of the shell and then decide that the site is unsuitable after they begin burrowing. The fact that the majority of the full sized burrows formed in juvenile shells were in the thickest sections of a shell, and that burrows did not connect, suggests borers can detect the shell thickness. Note that over a period of two and half months the worms did not bore through the inner surface of empty shells. Previous authors have suggested that polydorids do not break the inner surface of the shell because the abalone constantly produces extra layers of shell (Marshall & Day 2001). Thicker shell would actually allow the borers to increase the size of the burrows.

Size has an effect on both the number of boring worms present in the field, and on colonization, as only abalone 60 mm in length or larger became infested during this experiment. This suggests that larvae find it difficult to settle and bore into smaller shells. Kojima & Imajima (1982) found that the smallest *H. diversicolor* infested was 29 mm in length, but the majority of the boring occurred in abalone larger than 45 mm. Size also has a significant effect on the number of borers present in other mollusc shells (Smyth 1990). Perhaps this is to do with the smoothness of juvenile shells and the lack of crevices. Smaller shells are also very thin, making it difficult for a borer to form a burrow.

As reported previously by Leonart & Handlinger (1998), polydorids continue to live in the shell after the host has died, as long as the shell stays in a position that allows them to continue filter feeding. These worms will hasten the degradation of the shell, and thus play a role in the longevity of dead mollusc shells. This should also be considered by ecologists who measure mortality using empty shells, or study their use by hermit crabs (Smyth 1990).

Burrow Morphology and Growth Rate

The U-shaped burrows of *Boccardiella* MoV 3840 have not previously been observed. This seems to be an undescribed species. The shape of the burrow for *Dipolydora armata* concurs with those observed in several other substrates (Blake & Kudenov 1978) but it has not previously been observed in abalone. The U-shaped burrow for *Polydora woodwicki* has not previously been observed, and specimens of this species have been collected only once before.

We have shown that x-rays are useful to measure burrow expansion rates, although only a few borers could be kept alive for subsequent x-rays. Methods to improve survival during handling are needed, to facilitate further work to determine burrow expansion rates of other species.

The size and number of burrows formed in 72 days during the colonization experiment demonstrate how quickly polydorids can become established in, and damage shells. The X-rays show the extent of the damage well. This method will allow measurements of rates of infestation and will be an important tool to estimate burrow morphology and rate of expansion in different borer species and thus to determine which species cause greatest damage to the host. Extraction of borers from heavily infested shells does not pinpoint which species inflicted the damage.

Effects on Host Abalone

This study shows that boring affects the condition of abalone. Both condition indices, reflecting storage reserves in the muscle

and the health of the muscle, declined significantly with increased boring damage. The increased relative width of shells with more boring, and the other shape changes, indicates that the way heavily bored abalone enlarge their shells is different to those abalone with little boring present. The change in shell shape is obvious when lightly and heavily infested shells are compared. This change may be due to the disturbance caused by the deposition of extra shell layers (Marshall & Day 2001). Heavy boring at specific locations in the shell, such as the growing edge, may also cause the abalone to change the way it grows. The marketability of abalone as a live product and their shells as ornaments and jewelry is severely reduced by high levels of boring.

The mud blisters observed in abalone from Mallacoota have been observed in other molluscs, particularly oysters (Blake & Evans 1973), and can greatly reduce the internal volume of the shell. Thus a larger shell would be required to house the same soft tissue volume of the abalone. The species that caused these blisters also forms large burrows over the entire shell. It does not match any current descriptions from Australia and further work is urgently needed to determine if this species is an introduced or exotic species.

If the correlations reflect causation, then declines in condition indices with increased boring mean that boring affects the health and growth of abalone, and thus the muscle weight recovered by the fishery will be reduced by borers. Similar correlations have been found for other abalone and molluscs in general. *Haliotis diversicolor* had a reduced flesh weight when 10 or more polychaetes were present boring in the shell (Kojima & Imajima 1982). Other work on mussels and oysters has shown that heavy infestations by borers were associated with lower condition indices or reduced nutrient reserves (Kent 1979, Wargo & Ford 1993). In contrast, Clavier (1989) found no correlation between level of boring in *H. tuberculata* Linnaeus and the health of the abalone, but his study did not include heavily bored abalone, where the effect on muscle weight was found to be strongest in this study. Caceres-Martinez et al. (1998) found no significant effect of boring on condition indices of the oyster *Crassostrea gigas* (Thunberg), but again, their study did not include heavily infested oysters. They noted this was essential in determining the relationship between host and borer.

One would expect deleterious effects of borers on host condition because the shell thickening response would shift resources away from other functions. Bored *H. rubra* were found to increase shell secretion rates 4-fold (Marshall & Day 2001). Wilbur & Saleuddin (1983) suggested that one quarter to one third of the total energy of growth is required for shell deposition in molluscs. Thus substantial energy would be required for the increased shell thickening, with a corresponding decrease in resources for somatic growth or fecundity.

The correlation of borer infestation with an increased shell width to length ratio suggests reduced growth. Slow growth in *H. rubra* is indicated by increased width and height relative to length (Worthington et al. 1995). Abalone divers classify stocks in some areas as "stunted," because few abalone grow past the size limit (Wells & Mulvey 1995, Troynikov et al. 1998). Stunted stocks have both high, domed shells, and high levels of boring. Slowly growing abalone may reach older ages because they are not harvested, and thus accumulate many borers. Thus slow growth may lead to heavy boring, or the deleterious effects of boring may cause the stunted growth. Perhaps both effects occur. Further investiga-

tion of juveniles in stunted areas is needed to understand the link between boring and stunted growth.

Abalone extensively infested with sabellid polychaetes were reported to be less able to right themselves when turned over (Oakes & Fields 1996), apparently due to the doming of the shell due to abnormal shell deposition at the growing edge but perhaps also because of the diversion of resources to extra shell deposition. The effects of polydorids on shell shape are less severe.

Decreased growth, decreased muscle weights, and deformation of the shell would all reduce the profit of the commercial abalone industry directly. Polydorid borers may cause such effects. Reduced growth reduces fecundity, and boring weakens the shell, which would increase mortality. This in turn would lower the levels of fishing populations can sustain. If, as we suggest, borers

in abalone cause these effects, they deserve attention. Yet there has been so little research that even the risk of new introduced species affecting fishing areas cannot be assessed. This study provides methods for future work to study colonization, burrow morphology and expansion, and the effects on abalone hosts.

ACKNOWLEDGMENTS

The authors thank the Museum of Victoria and the Zoology Department and Dentistry Hospital at the University of Melbourne for the facilities provided and Ocean Waves Seafoods Pty Ltd. for the abalone. The authors also thank Prof. J. Clement, Cameron Dixon, and John Ahern for assistance and discussions, and referees for the many important suggestions.

DATA ON PINK ABALONE, *HALIOTIS CORRUGATA* (GRAY 1828) WITH INFESTED SHELLS FROM THE SAN BENITO ARCHIPELAGO, BAJA CALIFORNIA, MEXICO

F. CABALLERO-ALEGRÍA, J. A. RODRÍGUEZ-VALENCIA,* AND J. CASTRO-GONZÁLEZ

Instituto Nacional de la Pesca, CRIP-Ensenada, Carretera Tijuana-Ensenada Km 107, Parque Industrial Fondepert, El Sauzal, Baja California, Mexico

ABSTRACT This work presents abundance estimations of pink abalone (*Haliotis corrugata*, Gray 1828) with shells infested by epibionts from the San Benito archipelago (Baja California, Mexico). The first quantifications, undertaken at the end of the 80s, revealed that the highest abundances of infested abalone were concentrated around one of the three islands of the archipelago, where notorious differences in aspect and sizes between infested and normal exemplars were observed. Between 1989 and 1992, infested pink abalones from this location were commercially extracted, attempting to clean up the population. Extractions resulted in the dominance of normal exemplars. Nevertheless, 10 y later (year 2001), the abundance of infested pink abalone was again higher than that of normal pink abalone, and normal and infested organisms seemed to be bathymetrically segregated. In year 2001, differences in aspect between infested and normal organisms remained notorious, but differences in size were practically absent. Most of the infested exemplars were adults. Two morphotypes of infested pink abalone were identified: (a) abalone which shells are dome-shaped and which growth is vertically directed, with the surface homogeneously covered by epibionts and (b) abalone with flat and oval-shaped shells, which growth is horizontally directed, and edges usually free of epibionts.

KEY WORDS: abalone, *Haliotis corrugata*, epibionts, shell, infestation, Mexico

INTRODUCTION

In Mexico, all abalone species have high economic value. Nowadays, the production of meat and shell is supported by green *Haliotis fulgens* (Philippi 1854) and pink abalone *H. corrugata* (Gray 1828). Sometimes, shells of green abalone can be as expensive as the meat itself, whereas those of pink abalone usually occupy the second place in importance, because they accumulate high densities of epibionts. The presence of epibionts does not affect the quality of the meat, but some can perforate the shell destroying the mother-of-pearl. This kind of damage is typical for the sponge *Cliona* (Kojima & Imajima 1982), the spionid polychaete *Polydora* (Clavier 1992), and some sabellid polychaetes (Leighton 1998, Kuris & Culver 1999).

The knowledge about the effect of epibionts over Mexican abalone species is scarce. Alvarez-Tinajero et al. (2000) reported about the incidence of the boring clam *Lithophaga* over pink abalone and its repercussions over the shell marketing at Cedros Island. Cáceres-Martínez and Tinoco-Orta (2001) analyzed the effect of spionid and serpulid polychaetes over *H. rufescens*. Nothing is known about the frequency of infested abalone at wild populations. Ortiz-Quintanilla (1974) reported for the first time about a population of pink abalone from the middle island of the San Benito archipelago, where the incidence of infested abalone with sizes below the minimum legal size of capture (140 mm of shell length) was particularly high. Due to the appearance of the infested organisms, the local fishermen named them "dwarf abalones." Between 1989 and 1992 special permissions were granted for extracting infested abalones from the archipelago, attempting to clean up the population.

Here, we present the most important results of the quantifications of infested pink abalone undertaken between 1988 and 1991 at the San Benito archipelago, which up to now have remained unpublished. Additionally, results of the latest quantification un-

dertaken in July 2001 will allow us to know about the persistence of the infestation phenomenon in this area.

MATERIALS AND METHODS

The most important features of the San Benito archipelago (Fig. 1) were described by Rodríguez-Valencia and Caballero-Alegría (2002). The first quantification of infested pink abalone was undertaken in February 1988, randomly locating sampling points inside the fishing area (0–30 m depth) around the three islands, and using a 1 m²-quadrant as sampling unit. All abalone found inside the quadrant were collected. In this survey, 200 m² were explored around the westerly island, 225 m² at the easterly island, and 450 m² at middle island. After this attempt, quantifications for infested pink abalone were restricted to the middle island (October 1989, March 1990, and October 1991) using the method described by Rodríguez-Valencia and Caballero-Alegría (2002). The most recent survey was done in July 2001, again applying the method described by Rodríguez-Valencia and Caballero-Alegría (2002), at 86 randomly located sampling points (Fig. 1).

RESULTS

The Abundance of Infested Pink Abalone During 1988 to 1991

In February 1988, the abundance of infested pink abalone at the middle island of the archipelago was higher (0.3 abalone*m⁻²) than at the westerly and easterly islands (0.1 and 0.08 abalone*m⁻², respectively). Sixty percent of all the pink abalone captured during this survey was infested, and 96% of them were smaller than the minimum legal size of capture (140 mm of shell length). In October 1989, the abundance of infested pink abalone at the middle island was 0.2 abalone*m⁻², whereas at the other two islands was 0.1 abalone*m⁻². Ninety-eight percent of all the abalone collected around the middle island (36996 exemplars) was infested, and 89% of them were below the minimum legal size of capture. The most common epibionts observed over the shells were *Corallina* spp., hydrozoans, bryozoans, serpulid and spionid polychaetes, *Cliona celata*, and *Lithophaga plumula*. Normal and in-

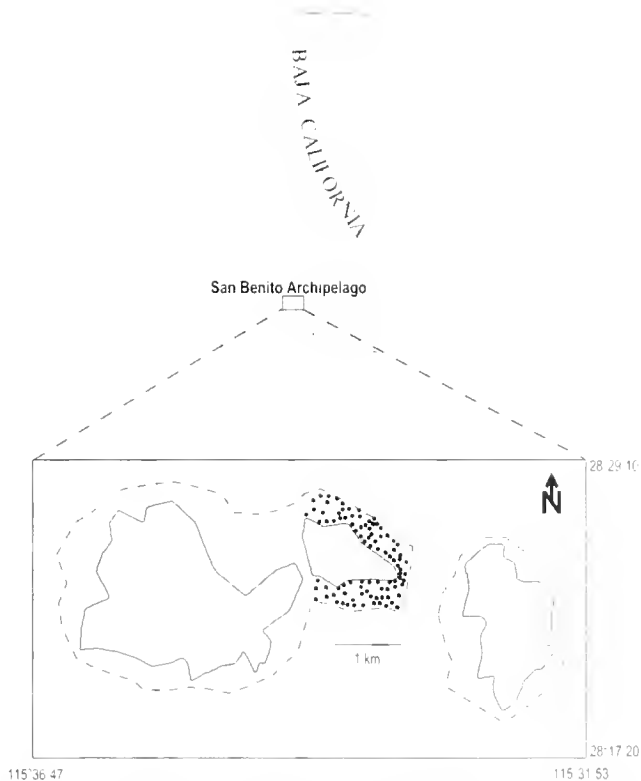

Figure 1. Location of the San Benito archipelago (the middle island is shadowed). Points around the middle island indicate the sampling stations for the survey undertaken in July 2001. The dashed line represents the 30 m isobath.

infested abalone differed markedly in size. In 1989, the modal size of infested organisms was 118 mm versus 140 mm in normal ones. In 1990, modal sizes were 124 mm versus 135 mm, respectively.

As a result of the special capture permissions for infested pink abalone granted to the local fishermen, 6.9, 12.9, 10.0, and 5.8 tones of meat were extracted from the middle island of the archipelago, in 1989, 1990, 1991, and 1992 respectively. In consequence, the abundance of infested pink abalone decreased ($0.2 \text{ abalone} \cdot \text{m}^{-2}$ in March 1990 vs. $0.05 \text{ abalone} \cdot \text{m}^{-2}$ in October 1991), whereas the abundance of normal pink abalone remained between 0.2 – $0.3 \text{ abalone} \cdot \text{m}^{-2}$. The contribution of normal pink abalone to the total catch increased from 2% in 1989, to 34% in 1992, whereas that of infested pink abalone below the minimum legal size of capture decreased from 40% to 4% for the same period. The modal shell length of infested pink abalone increased from 127 mm to 142 mm.

The Abundance of Infested Pink Abalone 10 Years Later

In July 2001, the abundance of infested organisms at the middle island was significantly higher than that of normal organisms ($0.1 \text{ abalone} \cdot \text{m}^{-2} \pm 0.03$ vs. $0.07 \text{ abalone} \cdot \text{m}^{-2} \pm 0.03$, respectively; $F_{(1,170)} = 5.0$, $P < 0.05$). Fifty-seven percent of all the pink abalone collected (294 exemplars) was infested. The highest abundance of normal pink abalone was concentrated between 10–20 m deep (52% of their total abundance), whereas 40% of the total abundance of infested pink abalone was found between 20–30 m deep.

Differences in appearance between normal and infested pink abalone were still marked (Fig. 2). In dorsal view, infested shells differ by having only one pair of open respiratory orifices; in ventral view their edges lacked a marked CaCO_3 accumulation band, reflecting a decreased horizontal growth. Nevertheless, differences between the mean shell lengths of normal and infested pink abalone were absent ($127.6 \text{ mm} \pm 1.6$ in infested abalone vs. $129.1 \text{ mm} \pm 2.2$ in normal abalone; $F_{(1,167)} = 1.2$, $P > 0.05$). Significant differences between the mean weight of muscle were also absent ($143.7 \text{ g} \pm 7.0$ for infested abalone vs. $145.6 \text{ g} \pm 9.0$ for normal abalone; $F_{(1,167)} = 0.1$, $P > 0.05$).

In pink abalone, the size of the muscular scar over the ventral face of the shell increases as the organism gets older; therefore, exemplars without or with small scars are younger than those with large and well-defined scars. This allowed us to build groups of relative age (Fig. 3): (1) Juveniles I, as exemplars, which shells lack of muscular scar; (2) Juveniles II, as organisms which shells have small muscular scars; and (3) Adults, as organisms which shells have large and well-defined scars. Four percent of the infested pink abalone was Juveniles I ($120 \text{ mm} \pm 8.0$ of mean shell length), 25% were Juveniles II ($128.5 \text{ mm} \pm 3.0$ of mean shell length), and 73% were Adults ($128.6 \text{ mm} \pm 1.0$ of mean shell length). The mean shell length between these three groups differed significantly ($F_{(2,166)} = 4.1$, $P < 0.05$), but differences were caused by the mean length of Juveniles I (after Tukey HSD Test).

Two morphotypes were recognized among infested abalones (Fig. 4). Organisms with almost perfectly rounded and dome-shaped shells represent the first type. The surface of these shells is homogeneously covered by epibionts. Flatted and oval-shaped shells, without dome appearance, represent the second type. Edges of these shells are usually free of epibionts. Morphotypes were named "vertical growth" and "horizontal growth," respectively. Sixty percent of all the infested pink abalone belonged to "vertical growth" being their abundance concentrated between 10–20 m in depth (55% of their total). The rest of the infested pink abalone (40%) belonged to the "horizontal growth" type, being mainly concentrated between 10–30 m deep (89% of their total).

DISCUSSION

Unfortunately, raw data of the first surveys were not captured and got lost, being only summarized in technical reports of our institution. This hinders the extraction of more information through additional analyses. It is probable that this data set represents the unique documentation about the temporal persistence of the infestation phenomenon by epibionts in abalone, since any other similar information has been published until now. As far as we know, any other attempt to clean up populations of infested organisms, as the one described here, has been done. This strategy, applied until 1992, apparently succeeded because the incidence of infested organisms decreased and the abundance of normal pink abalone remained practically constant. Nevertheless, the absence of the raw data set hinders the statistical confirmation. Ten years later, the abundance of infested abalone again surpassed that of normal exemplars at the middle island of the archipelago, but both showed lower abundance levels than those observed during 1988 to 1991 due to the regional decline in abalone populations (Guzmán-del-Prío 1992; Shepherd et al. 1998). Based on the yearly surveys undertaken at the archipelago (Rodríguez-Valencia

Figure 2. (a) Dorsal view of a shell belonging to a normal pink abalone. (b) Dorsal view of a shell belonging to an infested pink abalone. (c) Ventral view of a shell belonging to a normal pink abalone. (d) Ventral view of a shell belonging to an infested pink abalone. (e) Detail of the ventral edge of a shell belonging to a normal pink abalone. (f) Detail of the ventral edge of a shell belonging to an infested pink abalone.

& Caballero-Alegria 2002). We know that the incidence of infestation by epibionts remains highest around the middle island of the archipelago.

We believe that the abundance turnaround of infested abalone and the absence of differences in size between normal and infested organisms, observed in July 2001, are by-products of the fishery.

This may have occurred because infested pink abalone are not preferred by commercial divers, because their shells will not sell well; therefore, they are focused on the extraction of normal pink abalone. This leads to the reduction of abundance of normal organisms and the reduction of the mean size of normal abalone to sizes similar to those of infested pink abalone. This is supported by

Figure 3. Relative age groups based on the size of the muscular scar, located on the ventral face of pink abalone shells. (a) Juveniles I, without muscular scar. (b) Juveniles II, with small muscular scar. (c) Adults, with large and well-defined muscular scar.

findings of Rodríguez-Valencia and Caballero-Alegria (2002), indicating that between 1989 and 1999 the modal size of pink abalone at the archipelago has decreased.

We still do not have a clear explanation for the occurrence of two morphotypes of infested pink abalone. We hypothesize, that organisms showing "vertical growth" were infested at early ages and small sizes; therefore the epibionts crust covered the whole shell surface and hindered the continuation of horizontal growth. On the other hand, organisms with "horizontal growth" could have been infested when they were older and their shells were already oval-shaped. It is probable that the epibionts crust did not cover the whole surface, allowing the continuation of horizontal expansion. At the present, we are trying to find a method suitable to test this hypothesis.

This topic leads to the following interesting open questions that would be worthy to assess through experimental approaches: What are the reasons for the bathymetric segregations between normal and infested pink abalone, as well as between morphotypes of infested abalone? Are meroplanktonic larvae of some of the epibionts passively or actively retained around the middle island of the archipelago, leading to a higher larval settlement at this location? How comparable are densities and species composition of epibionts over the abalone shells with those over other hard substrata around the middle island (e.g. boulders, shells of other mollusks, and/or crabs exoskeletons)? Are there seasonal/yearly changes in the specific composition of epibionts over the pink abalone shells? Are there physiologic and/or genetic differences between normal and infested pink abalone? Are there chemical differences in shell composition between normal and infested abalone? Is the infestation degree dependent on ontogeny?

During these years we have been willing to find a method to get more accurate age estimations. Nevertheless, as Muñoz-López (1976) reported, deformed spires and damaged periostracs hinder the age determination using growth rings. Our relative age categories are similar to those defined by Muñoz-López (1976), after finding a good correlation between gonadal maturity and development of muscular scars (he used juveniles, lacking of muscular scar; preadults, with muscular scars slightly marked; and adults, with complete and well defined muscular scars). Talmadge (1964) also used similar classifications.

Fortunately, there are no differences in taste of the meat between normal and infested pink abalone. Nevertheless, shell deformations and shell weakness induced by boring epibionts (Oakes & Fields 1996) do have economic repercussions (Alvarez-Tinajero et al. 2000). We believe that the assessment of the remaining open questions and the analysis of temporal dynamics of infesting by epibionts at a fixed location are worthy tasks.

ACKNOWLEDGMENTS

We dedicate this work to the memory of our colleague A. L. Lelevier-Grijalva, who strongly contributed in the conception and development of the first versions of this manuscript. The authors sincerely thank our colleagues from the National Institute for Fisheries (Mexico) that helped during all the surveys. This work has been made possible thanks to the logistic support of the fishermen cooperative S.C.P.P. "Pescadores Nacionales de Abulón". A. Cota-Villavicencio provided valuable suggestions for this manuscript.

MICROSATELLITE DNA ANALYSIS OF SOUTHEAST AUSTRALIAN *HALIOTIS LAEVIGATA* (DONOVAN) POPULATIONS — IMPLICATIONS FOR RANCHING IN PORT PHILLIP BAY

BEN T. MAYNARD,¹ PETER J. HANNA,^{1*} AND JOHN A. H. BENZIE²

¹School of Biological and Chemical Sciences, Deakin University, Geelong, VIC 3217, Australia;

²Centre for Marine and Coastal Studies, University of New South Wales, Sydney, NSW 2052, Australia

ABSTRACT The genetic composition of greenlip abalone (*Haliotis laevis*) from Point Cook in Port Phillip Bay was examined prior to the aggregation of individuals from this site for ranching. The very thinly distributed natural population at Point Cook was believed to be of low genetic diversity, because the animals all originated from a single spawning event 5 y previously. Animals from Point Cook were compared with other *H. laevis* from two sampling sites within Port Phillip Bay, and two sites outside the Bay in Bass Strait, to examine their genetic diversity and origin. Variation was assessed at five microsatellite loci. Deviations from Hardy-Weinberg equilibrium (HWE) were observed at some loci in various populations, but the Point Cook population was in HWE at all five loci. Mean heterozygosity and number of alleles was similar in all populations. Hierarchical analysis of molecular variance indicated significant genetic variation among populations, but did not differentiate Port Phillip Bay from Bass Strait populations. Pairwise comparisons of multilocus F_{ST} and R_{ST} indicated significant genetic differences between Point Cook and some populations, as well as between other populations, but no consistent spatial pattern of differentiation was observed. There was no significant correlation between genetic and geographic distance. The level of genetic variation observed in the Point Cook individuals was similar to that in individuals from the other four sites, and sufficient to support a ranching program. However, this variation should be monitored to maximize genetic potential, and avoid commercially undesirable effects of inbreeding. Implications of this study in relation to the management of a ranching population in Port Phillip Bay are discussed.

KEY WORDS: microsatellites, genetic composition, *Haliotis laevis*, ranching population

INTRODUCTION

Australia is a major exporter of abalone, supplying an estimated 81% of fresh and frozen product and 67% of canned product to international markets (Brown 1997), worth over AUD\$249 million (Australian Bureau of Agricultural and Resource Economics 2002). Blacklip abalone, *Haliotis rubra*, is the main commercial catch in the state of Victoria, contributing 7,110 t (worth AUD\$283.8 million) over the past 5 y, during which time greenlip abalone, *H. laevis*, contributed only 12 t (worth AUD\$474,000) (Anon 2002). The *H. laevis* fishery is on the verge of closure, and the maintenance of an export industry for this species may only be possible through aquaculture.

Deakin University research, in conjunction with Melbourne Abalone Pty. Ltd., is testing the suitability of ranching abalone in Port Phillip Bay, a large protected Bay relatively isolated from the open sea of the Bass Strait. *H. laevis* are being accumulated from Point Cook, a northwestern area of Port Phillip Bay, where the dispersed nature of the population suggests they are unlikely to reproduce naturally. Shepherd (1986) found that adult *H. laevis* aggregate prior to and during spawning, and that aggregation densities of no less than 0.2 animals per m² were essential for successful spawning. Individuals in the Point Cook region are usually more than 100 m apart.

Because the Point Cook population was first observed by divers 4 y ago as spat, it is suspected that these animals are very closely related through a rare spawning event a year prior. It is likely clockwise currents, a predominant pelagic influence in Port Phillip Bay (Black & Mourtikas 1992), could have dispersed larvae to Point Cook from either of the two known *H. laevis* sources in the Bay at Grassy Point or Queenscliff (Fig. 1). If this were the case, then the Point Cook population could have reduced genetic diversity, because the cohort may have originated from only a few animals. This may give rise to difficulties in a ranching population

derived from these animals, given the higher risk of deleterious inbreeding effects being expressed.

Microsatellites, first described by Weber and May (1989), are short segments of 2–6 base pairs (bp) repeated tandemly in tracts of up to 100 bp long (Chambers & MacAvoy 2000). Microsatellites have been successfully utilized for population genetic research in a range of commercially important and endangered aquatic species, including abalone (Elliott et al. 2000, Huang et al. 2000, Withler et al. 2001, Conod et al. 2002, Evans et al. 2000b, Selvamani et al. 2000, Selvamani et al. 2001, Hanna et al. 2000, Sweijd et al. 2000, Kirby et al. 1998).

Microsatellite primers developed for *H. rubra* have also been successfully utilized with *H. laevis* (Evans et al. 2001, Robinson & Baranski pers. comm.). We present here the results of a study using five of these microsatellite loci to determine the genetic diversity and possible source(s) of animals being used to develop an artificial population of *H. laevis* for a ranching trial.

MATERIALS AND METHODS

Abalone Samples

Epipodial tissue samples were collected from live *H. laevis*, of >100 mm in length, at three Port Phillip Bay sites and two Bass Strait sites during 2002 (Fig. 1). Field sampling was undertaken at Point Cook ($n = 19$) and Grassy Point ($n = 20$), while Queenscliff ($n = 29$), Torquay ($n = 21$) and Phillip Island ($n = 30$) samples were taken at commercial abalone processing facilities. The removal of an epipodium for tissue sampling is considered nondestructive (Withler et al. 2001).

Each epipodium was placed in a 1.5 mL Eppendorf tube containing 70% v/v ethanol and stored on ice during transfer to the laboratory. The ethanol was removed and samples rinsed in 1.0 mL sdH₂O for 5 min to remove exopolysaccharides and trace amounts of ethanol. Excess sdH₂O was then removed and the samples stored at –80 °C until analyzed.

DNA Extraction, Amplification, and Scoring of Microsatellite Loci

Epipodia (~25 mg) were minced with separate sterile scalpel blades and transferred to 1.5-mL Eppendorf tubes, containing 0.5 mL of DNAzol (Invitrogen). Each homogenate was mixed by gentle pipetting, followed by vigorous shaking for 10 min, before centrifugation at 13,500 rpm in a bench centrifuge (Microcentaur) for 10 min at room temperature. Supernatants were transferred to new 1.5-mL tubes and DNA precipitated by the addition of 0.5-mL 100% v/v ethanol per mL of DNAzol. The samples were mixed by inversion, and stored at -20°C for 1 h. To pellet DNA, samples were centrifuged as before. The supernatants were removed and the pellets washed with 1.0 mL 95% v/v ethanol. Each tube was inverted three to six times before centrifugation as before. The ethanol washes were repeated, and the pellets dried at 37°C for 5 min before resuspension in 50 μL of 8 mM NaOH. The resulting DNA solutions were adjusted to pH 7.5 with the addition of 159 μL of 0.1 M HEPES per 1 mL of 8 mM NaOH solution. DNA samples with spectrophotometric purity ratios ($\text{OD}_{260}:\text{OD}_{280}$) between 1.5–2.0 and concentrations of ≥ 20 ng/ μL were stored at -20°C until required.

Any DNA sample with a purity outside of the range 1.5–2.0 was made up to 200 μL with 8 mM NaOH, to which was added 300 μL of sdH_2O and an equal volume (500 μL) of phenol:chloroform:isoamylalcohol (25:24:1). The sample was mixed by inversion before centrifugation as mentioned earlier. The aqueous phase was collected and transferred to a fresh tube. DNA was precipitated from solution by the addition of 2 volumes of 100% v/v ethanol. The sample was stored at -20°C for 30 min before centrifugation as earlier. The DNA pellet was washed twice with 95% v/v ethanol and then dried. The DNA pellet was resuspended in 50 μL of TE buffer.

Five polymorphic loci, viz *RUBGT1* (Huang & Hanna 1998, Genbank Accession Number AF027572), *cmrHr2.14* (Evans et al. 2000a, AF194957), *cmrHr2.23* (Evans et al. 2001, AF302832), *Hrub4*, and *Hrub12* (provided in confidence by N. Robinson and M. Baranski), were amplified from *H. laevigata* genomic DNA.

An FTS-320 Thermal Sequencer (Corbett Research) was used for PCR amplifications, comprising 100 pmol forward and reverse primers (PROLIGO), 1 \times PCR buffer (Invitrogen), 2 mM MgCl_2 (Invitrogen), 2.5 mM each dNTP (Roche), 1 U *Taq* polymerase (Invitrogen), and 200 ng template DNA, made up to 25 μL with

sdH_2O . PCR cycle conditions were 94°C for 2 min; then 35 cycles of 94°C for 15 sec, locus-specific annealing temperature for 30 sec, 72°C for 1 min; and finally 72°C for 10 min. Annealing temperatures were 52°C for locus *cmrHr2.23*, 54°C for locus *cmrHr2.14*, and 55°C for loci *RUBGT1*, *Hrub4*, and *Hrub12*.

PCR samples were mixed with formamide loading buffer (FLB), then denatured at 95°C for 4 min and held on ice. Microsatellite alleles were separated as per Huang et al. (2000), together with three lanes of 10 bp DNA ladder (Invitrogen) in FLB. A nonmutagenic silver staining protocol was used to resolve separated PCR fragments (Ludwig et al. 1989, Caetano-Anolles et al. 1991). Microsatellite DNA sizes were determined as per Huang et al. (2000).

The allele present in the most common homozygote specimen of each locus was sequenced, after TA cloning into pCR2.1 (Invitrogen), to ratify that the product amplified contained the repeat length equal to that being scored after PAGE and silver staining. The correct number of repeats was observed within each sequence, viz sizes 153 bp, 282 bp, 259 bp, 199 bp, and 242 bp for loci *RUBGT1*, *cmrHr2.14*, *cmrHr2.23*, *Hrub4*, and *Hrub12* respectively.

Statistical Analysis

Allelic frequencies were calculated using MS Excel. Arlequin version 2.001 software (Schneider et al. 2000) was used to statistically analyze genotypic data. Observed (H_o) and expected (H_e) heterozygosities were calculated for each locus at each site. Conformity to Hardy-Weinberg Equilibrium (HWE) was analyzed by exact tests using a Markov chain. Multilocus R_{ST} values (assuming the Step-wise Mutation Model for microsatellite evolution) and F_{ST} values (assuming the Infinite Allele Model) were calculated for each population pairing. Probability values for HWE and pairwise tests were Bonferroni-adjusted to account for multiple comparisons (Rice 1989). Mantel tests to analyze correlations between F_{ST} or R_{ST} genetic distances and geographic distance (direct water distance) matrices were also used. Analysis of molecular variance (AMOVA) was used to partition genetic variation into hierarchical levels (among populations, F_{ST} ; among groups of populations, F_{SC} , viz Port Phillip Bay and Bass Strait; and among populations within groups, F_{CT}) to test for spatial structure at different scales.

RESULTS

The number of alleles per population ranged from 2–4 at *cmrHr2.23*, 2–5 at *Hrub4*, 5–8 at *cmrHr2.14*, 7–11 at *RUBGT1*, and 7–14 at *Hrub12* (Table 1). Mean number of alleles ranged from 5.2 at Grassy Point to 8.0 at Queenscliff and Phillip Island (Table 1).

Significant homozygote excesses were observed in 8 out of 25 locus by sample tests, with no obvious association with a particular locus or population (Table 1). Samples from Point Cook were in HWE at all five loci (Table 1). Mean heterozygosity ranged from 0.394 at Grassy Point to 0.596 at Queenscliff (Table 1).

Ungrouped AMOVA comparing all sites across all loci showed significant genetic subdivision among populations ($F_{ST} = 0.011$, $P < 0.001$). However, when populations were grouped into Port Phillip Bay (Point Cook, Grassy Point, Queenscliff) and Bass Strait (Torquay, Phillip Island) sites, there was no significant difference between groups ($F_{CT} = 0.001$, $P = 0.075$), but there were still differences among populations within groups ($F_{SC} = 0.010$, $P < 0.001$).

H_o , observed heterozygosity; H_e , expected heterozygosity.

* Significant departure from HWE ($P < 0.01$ after Bonferroni correction for multiple tests); *n*, number of individuals scored.

F_{ST} and R_{ST} values from comparison of population pairs showed statistically significant ($P < 0.001$) differences between some populations (30% to 40% of comparisons), but F_{ST} and R_{ST} values were significant for different populations except for Point Cook × Phillip Island, where both were significant (Table 2). Except for significant differences between Torquay with both Queenscliff and Phillip Island using R_{ST} , all other significant differences were between Point Cook and the other populations (Table 2). No obvious differences in the frequency of dominant alleles, or the presence of rare and unique alleles among populations, were observed to account for pairwise results (data not shown).

Mantel tests of the relationship between genetic distance and direct water distance were not statistically significant for F_{ST} ($r = 0.223$; $P = 0.292$) and for R_{ST} ($r = 0.310$; $P = 0.194$).

DISCUSSION

H. laevigata were rare (less than 1% of the frequency of *H. rubra* at Point Cook; abalone divers W. Butler and B. Cronin, pers. comm.), and were also low in numbers at the other two Bay

sites. Therefore, sample sizes were limited to approximately 20 within Port Phillip Bay. Although below sample sizes used in allozyme assays (e.g., 84 *H. rubra* per population, Brown 1991; 66 *H. laevigata* per population, Brown & Murray 1992), these were

TABLE 2.

Pairwise multilocus F_{ST} (above diagonal) and R_{ST} (below diagonal) values of five microsatellite loci for five sites.

	Point Cook	Grassy Point	Queenscliff	Torquay	Phillip Island
Point Cook	—	0.039*	0.017	0.025*	0.047
Grassy Point	0.102	—	-0.006	0.001	-0.002
Queenscliff	0.143 [†]	0.062	—	-0.007	0.007
Torquay	-0.018	0.011	0.093*	—	0.002
Phillip Island	0.280*	0.085	0.020	0.126 [†]	—

* Significant value at $P < 0.01$ after Bonferroni correction for multiple tests.

within the range of recent microsatellite analyses on molluscan species that have provided useful data (e.g., 10 *H. rubra* per population, Huang et al. 2000; 10–59 brown mussels per population, Holland 2001).

Small sample sizes are common with species that are endangered, but such small sample sizes may fail to detect relatively common alleles that contribute to significant differentiation among populations (Berg & Berg 2000). Differences in sample size, and in the cohorts sampled, between populations on small sampling scales can bias comparisons of genetic diversity, although this factor would impact allelic variation more than heterozygosity. Further work at our study site will improve discriminatory power by increasing sample size and sampling effort, simultaneously reducing the probability of Type I and II errors (Richardson et al. 1986). More individuals would need to be typed before several unique alleles observed in the Point Cook population, and other alleles uniquely present elsewhere, can be used for stock identification.

Genetic Diversity

Levels of microsatellite polymorphism were similar to previous studies of abalone in southern Australia (Huang et al. 2000, N. Elliot pers. comm.). Levels of allelic variation in the Point Cook population were at the low end of the range for four out of the five loci tested in the present survey. Huang et al. (2000) also found limited genetic diversity in the Point Cook *H. rubra* population, where only two alleles were observed at locus RUBGAC1 compared with four or more in oceanic populations. There were few significant deviations from HWE, concordant with results from previous genetic studies of abalone (Hamm & Burton 2000, Hancock 2000, Conod et al. 2002). The fact that heterozygote deficits were not found at all loci showing significant differences between populations suggests that the Wahlund effect (resulting from the mixing of populations that differ in gene frequency) is not responsible for the deficits observed. Gel images were also carefully checked according to a suite of widely used criteria (B. Huang pers. comm.). Although null alleles have been ruled out for locus RUBGT1 in *H. rubra* (Huang et al. 2000), Conod et al. (2002) concluded that null alleles were the most likely explanation for homozygote excess observations at *cmrHr2.14* and *cmrHr2.23*, and these may explain the deficits heterozygote in *H. laevigata*.

Spatial Structure

Although there were significant differences between the *H. laevigata* Point Cook population and other Port Phillip Bay and Bass Strait populations, there was no evidence for a consistent difference between Bay and Strait populations. This information contrasts with published data for *H. rubra*, where the Point Cook population was genetically distinct from oceanic populations in the central Victorian fishery management zone ($\Phi_{PT} = 0.077$ – 0.199 , $P < 0.001$ – 0.027), believed to result from the semi enclosed geography of Port Phillip Bay (Huang et al. 2000).

The level of genetic subdivision in *H. laevigata* populations found in the present study (overall $F_{ST} = 0.011$, $P < 0.001$) is lower than that recorded for *H. laevigata* by Huang (1998) in populations throughout Southern and Western Australia using randomly amplified polymorphic DNA ($\Phi_{PT} = 0.184$ over all populations, $\Phi_{RT} = 0.131$ among states, $\Phi_{PR} = 0.107$ among three Western Australian populations), and by Brown and Murray

(1992) and Shepherd and Brown (1993) using allozymes ($F_{ST} = 0.014$). Genetic subdivision in coastal populations of the related species, *H. rubra*, was also greater (overall $F_{ST} = 0.077$) (Huang et al. 2000).

Previous surveys of genetic variation in abalone species in Australia have demonstrated both strong patterns of isolation by distance in *H. rubra*, with average neighborhood sizes estimated to range from 60–70 km (Huang et al. 2000) to 500 km (Brown 1991), and no relationship between geographic and genetic distance among samples from Victoria and Tasmania (Conod et al. 2002). The present study found no significant correlation between genetic and geographic distance. An estimate of neighborhood distance based on comparison of the Point Cook and Phillip Island populations, separated by 100 km, supports data from Huang et al. (2000), and concurs with inferences from ecological studies that abalone are locally recruited (McShane et al. 1988, McShane 1992, Prince et al. 1988).

The present study provided no evidence that Port Phillip Bay populations constitute a group separate from Bass Strait populations (in contrast to *H. rubra* [Huang et al. 2000]), but the Point Cook population was differentiated from all but one other population using F_{ST} (and none of the other populations were differentiated from each other). F_{ST} is influenced to a greater degree than R_{ST} by shifts in allele frequencies, and the greater differentiation with F_{ST} than with R_{ST} supports an interpretation that differences between the Point Cook population and all others is recent and related to a founder effect rather than the accumulation of differences resulting from mutation.

The spawning of abalone is affected by several local environmental factors (Shepherd & Laws 1974, Sasaki & Shepherd 1995). Subsets of animals in close proximity can spawn asynchronously (McShane et al. 1986) or exhibit independent spawning seasons (Shepherd & Laws 1974), providing the opportunities for local selection. Drew et al. (2001) demonstrated that Port Phillip Bay *H. rubra* were less affected than Bass Strait animals by heat and salinity, and differ in physiology (e.g., the inability of oceanic specimens to volume regulate compared with Point Cook abalone). This difference may reflect physiologic adaptation, but could also reflect adaptation by selection to the Port Phillip Bay environment (which experiences greater salinity, temperature, and nutrient input extremes than Bass Strait) over the 8,000 y since the Bay was formed. The lack of significant differences between the two groups (Port Phillip Bay and Bass Strait) of *H. laevigata* populations in the present study suggests that none of the molecular markers used are subject to selection themselves, or on closely linked loci, and that the differences observed are likely to reflect sampling effects associated with high variance in reproductive success between matings and founder effect. However, this data does not preclude adaptation to the Port Phillip Bay environment.

Ranching Implications, Recommendations, and Future Work

The genetic diversity of the *H. laevigata* population assimilated for a ranching trial was at the lower end of the range for other populations sampled. The differences observed between this population and others in Port Phillip Bay are consistent with a recent founder effect or variance in reproductive success. This suggests it should be feasible to add diversity to the ranching population using individuals collected from elsewhere. Given the possibility that Port Phillip Bay animals may differ physiologically from those at

ocean sites it would be prudent, until more information on this point is available, to use only animals from Bay sites. Fifty to 100 abalone broodstock of equal sex ratio need to be used to produce juveniles to maintain genetic diversity (Withler et al. 2001). It has been shown that mass matings do not necessarily ensure a large number of adults contribute to the next generation (Hedgecock & Sly 1990). It will also be important to manage breeding of the Point Cook population to avoid mating close relatives. Therefore, methods of single pair mating may need to be developed, and the population will need to be monitored to ensure genetic management objectives are met.

ACKNOWLEDGMENTS

The authors thank Dr. Nick Robinson and Matt Baranski from the Victorian Institute of Animal Science, for provision of primer sets *Hrub4* and *Hrub12*; Darren James and Wayne Butler for assistance with collecting fresh tissue samples; Tony Smith (Bay City Seafarm), Kaz Bartaska (Lonimar Australia Pty Ltd), and Fred Glassbrenner (Australian Abalone Exports Pty Ltd), for providing samples of live abalone tissues. The authors also thank two anonymous reviewers and Dr. Chris Burrige from Deakin University, whose comments improved the quality of this manuscript.

MEASURING ABALONE (*HALIOTIS SPP.*) RECRUITMENT IN CALIFORNIA TO EXAMINE RECRUITMENT OVERFISHING AND RECOVERY CRITERIA

LAURA ROGERS-BENNETT,^{1,2,*} BRIAN L. ALLEN^{1,3} AND GARY E. DAVIS⁴

¹California Department of Fish and Game, Bodega Bay, California 94923; ²U.C. Bodega Marine Laboratory, PO Box 247, Bodega Bay, California 94923; ³Squaxin Island Tribe, 2952 S.E. Old Olympic Hwy, Shelton, Washington 98584; ⁴Channel Islands National Park, 1901 Spinnaker Dr., Ventura, California 93001

ABSTRACT Abalone populations in southern California have declined dramatically since the 1950s when they supported a multi-species, commercial, and recreational fishery producing more than 3,000 t per year. Today the commercial fishery is closed statewide and the recreational fishery is closed south of San Francisco. In contrast, red abalone, *Haliotis rufescens* (Swainson, 1822), populations in northern California continue to sustain a 1,100 t per year free-diving recreational fishery. We used standardized Abalone Recruitment Modules (ARMS) made of half cinder blocks (area = 2.6 m²) to compare the recruitment of juvenile abalone in northern California, where stocks are abundant, with southern California where stocks have declined. We compared the abundance of abalone inside ARMS ($n = 12$) in Van Damme State Park (VDSP), northern California with abalone inside ARMS ($n = 82$) in the Channel Islands National Park from 2001 to 2003. Abalone densities on the reefs surrounding the ARMS at VDSP, averaged 8300/ha compared with abalone densities of 30/ha on reefs in three of the northern Channel Islands. Red, flat abalone, *H. walallensis* and pinto abalone, *H. kamtschaticana kamtschaticana* were found in the northern ARMS, whereas in the south red, pink, *H. corrugata*, threaded, *H. kamtschaticana assimilis*, and the endangered white abalone, *H. sorenseni*, were rare in the southern ARMS. Abalone were 30 times more abundant inside the ARMS in the north (5.30/ARM) compared with the south (0.18/ARM). Similar numbers of abalone were found in all 3 years in the ARMS in northern (69, 69, and 53 abalone) and southern California (14, 11, and 20 abalone). The majority of abalone in both the north and the south were less than 100 mm in shell length. Ironically, the rare flat abalone was more abundant in the north, than pink abalone were in the south, a species which once supported a major fishery. Clearly, abalone stocks in southern California are so low that recruitment is failing, despite their potential high fecundity and the fishery closure. These results demonstrate that ARMS can be used to monitor recruitment in the northern fishery, as well as establish quantitative recovery criteria to assess abalone restoration efforts that are desperately needed in the south.

KEY WORDS: juvenile abalone, abalone recruitment modules, monitoring, recruitment failure, abalone restoration

INTRODUCTION

Abalone populations in California once supported major fisheries, landing in excess of 3000 metric tons (t) per year (Cox 1962). Population declines, however forced the closure of both the recreational fishery south of San Francisco and the commercial fishery statewide in 1996. Populations in the south suffered serial depletion of five species within the *Haliotis* spp complex (Dugan & Davis 1993, Karpov et al. 2000). The white abalone, *H. sorenseni*, is now on the endangered species list and the primary cause of their decline has been attributed to overfishing (Hobday et al. 2001). In contrast, red abalone, *H. rufescens*, populations are still abundant in northern California where there is an active free-diving recreational fishery. Landings in the recreational fishery have been stable, averaging 1165 t in the mid 1980s (Tegner et al. 1992) with little change in 2000 (1238 t) (CDFG unpubl. data). Today, there is a need to quantify juvenile abalone recruitment in California to better manage fished populations in the north and to assess the status of depleted stocks in the south since the fishery closure. Specifically, temporal patterns of juvenile abundance can be used to assess the strength of future year classes entering the fishery as well as set restoration targets for populations following natural recovery or restoration efforts.

Recruitment of abalone, however, is difficult to quantify. Studies of larval dispersal and recruitment are rare (but see Sasaki & Shepherd 1995), with only a handful of studies examining the density and distribution of newly settled abalone (Prince et al. 1987, McShane & Smith 1991, Sasaki & Shepherd 2001). An

examination of densities of newly settled abalone (recruiting to the benthos) has been advocated for to quantify stock-recruitment relationships and density dependent survival, but these studies are impeded by the difficulties of sampling (McShane & Smith 1988). Most recruitment studies focus on the abundance of juvenile or young of the year abalone, sometime after settlement, when they are visible to divers (Sainsbury 1982, Shepherd & Turner 1985, Prince et al. 1988). Juveniles may be better predictors of the numbers of abalone surviving to become adults as compared with larval and newly settled abalone. Juveniles however, are also difficult to census (Yamaguchi 1975) sometimes requiring habitat destruction especially on complex rocky reefs.

Artificial structures made of cinder blocks have been used as standardized sampling units (Davis 1985) for juvenile abalone in southern California (Davis 1995). However, few juveniles have been found within these modules suggesting either recruitment failure, as is consistent with reef surveys showing little recruitment and few adults, or the modules are poorly suited to assess juvenile abalone in the wild. Recruitment overfishing may be difficult if not impossible to quantify (Harrison 1986, McShane 1992) because a sharp decrease in recruitment in species such as abalone with high individual fecundities may not occur (Harrison 1986).

Here we compare the numbers of juvenile abalone inside standardized recruitment modules made of cinder blocks deployed in northern California where densities of abalone are high, with southern California where densities are low. We examine the species composition, quantity, and size of juvenile abalone occurring inside abalone recruitment modules in 2001 and 2003. We quantify abalone populations on the natural rocky reefs surrounding the recruitment modules in both the north and south and compare them

*Corresponding author. E-mail: rogersbennett@ucdavis.edu

with the abalone inside the modules. We highlight the usefulness of collecting a time series of juvenile abalone recruitment information in California to aid in fishery management and evaluate the impacts of restoration programs. We examine the current status of abalone recruitment in southern California by comparing modern densities in the southern modules with the north and the south 10 years ago. We discuss the evidence for recruitment failure in southern California and the need for establishing measurable restoration goals.

MATERIALS AND METHODS

Northern California

Standardized abalone recruitment modules (ARMs) were deployed at Van Damme State Park (VDSP) (lat. 39°16'08"N, long. 123°47'58"W), northern California in August 2000 (Fig. 1). ARMs

were originally designed by E. Ebert and were made of concrete cinder blocks cut lengthwise, stacking the blocks five high and enclosing them in a wire frame (Davis 1995). Here, the design was modified to enhance resistance to intense wave action by using welded rebar cages, widening the block cube to lower the profile, stacking the blocks three high (rectangle measuring 813 mm × 610 mm × 305 mm high). The surface area of the blocks in each of the modified northern ARMs was 4.8 m², of which 2.6 m² was sheltered area created by the sides, top, and bottom of each "letter m."

VDSP is a popular and productive recreational abalone diving site dominated by rocky reef with seasonally abundant *Nereocystis* kelp canopy, a subcanopy of *Pterogophora* and numerous subtidal red algae including *Cryptopleura*, *Gigartina*, and *Iridacea*. Upright and encrusting coralline algae are also abundant. An estimated 25,500 (±5,430) red abalone were taken from VDSP in 2002 (CDFG unpubl. data).

Twelve ARMs were deployed between 9 and 12 m in three

Figure 1. A map of California showing sites in both northern and southern California where ARMs were deployed and abalone recruitment was monitored.

groups of four. The modules were placed 3–6 m apart within the cluster of four. The northern cluster was approximately 140 m from the central cluster. The southern cluster was 710 m from the central cluster. Each ARM was bolted into the rocky substrate using 6-inch stainless lag bolts in each of the four corners and in the center of the module. Holes for the 5 bolts were drilled using a Chicago pneumatic drill with a 0.25 inch bit.

The ARMs were surveyed annually in August. ARMs were in place 1 y before the surveys began in August 2001, 2002, and 2003. One dive team surveyed each ARM, opening the lid and carefully removing each block counting and measuring all of the invertebrates and fishes inside the ARMs. Organisms outside or on the cage were not sampled. Organisms too numerous to count were gently swept into fine mesh bags (2 mm) to be counted and measured at the surface. Organisms cemented to the brick were measured and quantified underwater. Each block was set to the side while the next block was removed and the animals quantified. When the survey was completed, divers reassembled the ARM and replaced the lid securing it with wide cable ties. Each ARM took two divers approximately 40 min to survey.

Abalone density on the adjacent natural reef was quantified annually in August from 2000 using transects at depths between 8 and 16 m. Each transect (1m × 5m) was searched invasively for abalone in 2000 ($n = 29$), 2001 ($n = 13$) and 2002 ($n = 32$). Invasive searching targeted small cryptic abalone and included looking in rock crevices, turning large rocks and small cobble, in coralline algae, and under sea urchins.

Southern California

ARMs have been deployed and surveyed by the National Parks Service's, Kelp Forest Monitoring Program in the northern Channel Islands since 1989 (Davis et al. 1997). These ARMs were cube shaped and slightly taller and narrower than the ARMs deployed in northern California (see details of the modifications required for the northern modules above). Each cage is made of plastic coated wire mesh (51 mm × 102 mm). The southern modules measured 600 mm × 600 mm × 500 mm high. Twenty half-cinder blocks were arranged four in a layer and stacked 5 layers high leaving the center core of the cube open. Each habitat provided 5.0 m² of which 3.0 m² was sheltered habitat created by the inside arches of the letter "m" which is comparable to the area of the northern California modules. The major differences between the southern and the northern module design was that the northern design had a lower profile, 18 half blocks and was bolted into the substrate whereas the southern modules were taller and more cube shaped, with 20 half blocks, an open core and were not bolted in place.

In 2001, 82 ARMs were sampled from three sites on Anacapa Island, five sites on Santa Cruz Island and two sites on Santa Rosa Island using the methods described earlier (Fig. 1). Each site comprised between 6 and 15 ARMs. Sites with 15 ARMs had three clusters of 5 ARMs each; at sites with only 6 or 7 all ARMs were grouped together in a single cluster. The majority of these sites were on the southern leeward side of the islands. In 2002, 84 ARMs were sampled and in 2003 at the same sites and islands 82 ARMs were sampled.

The density of adult red, pink, and green abalones were enumerated along transects on the natural reef. Adult abalone abundances were determined at each of the three islands with the ARMs. Depths of the transects at the three islands ranged from 5–16 m at Anacapa, 8–18 m at Santa Rosa and 4–18 m at Santa

Cruz Island. Deep-water species such as white and threaded abalone would not be found at these depths nor would shallow green abalone. A fixed reference line 100 m in length was bolted to substrate. Transects were placed perpendicular to this fixed reference line at random intervals. Transects covered an area 3 m × 20 m (60 m²). Twelve transects were completed at each site. Three sites were monitored at each of Anacapa Island (total area searched 2,160 m²) and Santa Rosa Island (2,160 m²) whereas 5 sites were monitored at Santa Cruz Island (total 3,600 m²).

The number of ARMs or replicates needed to detect "true" differences in the mean number of abalone in the north compared with the south was estimated using the test for sample size and the iterative method (Sokal & Rohlf 1981).

RESULTS

Abalone in the ARMs

Many more abalone were found inside the ARMs in northern compared with southern California in all 3 y (2001–2003) (Tables 1, 2). The number of abalone found inside the ARMs was consistent over the 3-y period (Tables 1 and 2). In the north 5.3 abalone were found per ARM. This was 30 times more abalone than observed in the south where the average was 0.18/ARM. In the north, three species of abalone were found inside the modules red flat and pinto abalone, whereas in the south, three species and one subspecies of abalone were found including two deep-water abalone (white and threaded abalone), albeit in very low numbers. In southern California, red, pink, white, and threaded abalone were found inside the ARMs in 2001–2003. In previous years, green abalone, *H. fulgens*, have also been observed in the ARMs (5 total in 10 y).

There was an 80% chance of detecting at least a 10% difference in the means of juvenile abalone density in northern compared with southern California at the 0.05 significance level with a sample size of 9 or more ARMs in each region.

Abalone on the Natural Reef

Abalone density on the natural reef surrounding the ARMs differed substantially between northern and southern California (Table 3). In northern California, abalone were found at high densities, while in southern California densities were near zero. Abalone density in the north averaged nearly 8500 abalone/ha (SD 2,302/ha) between 2000 and 2002 (Table 3). Of the 679 abalone measured in the north, 669 were red abalone, 9 were flat abalone and 1 was a pinto abalone (Table 3). Furthermore, abalone were abundant both shallower and deeper than the surveys. The density

of flat abalone was higher in the ARMs (4.8 abalone m^{-2}) than on the surrounding natural reef (0.012 abalone m^{-2}) in the north.

Few abalone were observed during the surveys at the three Channel Islands. No abalone were observed at Santa Cruz Island on any of the surveys. In the south, white and threaded abalone were found inside the ARMs but were absent from the shallow surveys of surrounding reef, at the depths surveyed (Tables 2 and 3). At Anacapa Island only 7 pink abalone were observed over the 3-y period during which 6,480 m^2 were searched. At Santa Rosa

Island abalone densities were slightly higher with 20 red abalone observed (31/ha) in the same area searched (Table 3). In the south, the numbers of adult abalones were consistently low, with abalone found at a small fraction (3/11) of the total number of sites.

Size Frequency Distributions

Small (<50 mm) and large abalone were found inside the ARMs in both northern and southern California. In the north, a

peak in young of the year abalone (<30 mm) was observed in 2001, but this peak was less pronounced in 2002 when more midsize juvenile abalone (50 mm) were observed in the size frequency distribution (Fig. 2). In the south, all the abalone observed in the ARMs were small except one adult (Fig. 2).

Qualitatively, the shape of the size frequency distribution at the small end (left side) was relatively similar in 2002 inside the ARMs compared with on the natural reef. This was not the case in 2001 when more juveniles in the 20-mm size class appeared in the modules than in surveys of the natural reef (Fig. 3). Overall, many more adult abalone (>100 mm) were observed on the transects over the natural reef compared with the ARMs suggesting the ARMs are not suitable for sampling adults. In southern California, too few adult red ($n = 20$) and pink abalone ($n = 7$) were observed on the natural reef to warrant comparing their size distribution with the sizes of the juveniles inside the ARMs.

DISCUSSION

The dynamics of abalone recruitment and the nature of the stock-recruitment relationship remains poorly understood, yet has important implications for management and restoration. In this study, we found recruitment failure (0.18/ARM) in southern California where adult densities are two orders of magnitude below the proposed minimum viable population size (2,000/ha) (Shepherd & Brown 1993). Furthermore, we found that abalone recruitment in southern California has declined 20-fold over the past decade, despite the fishery closure. In 1990 ($n = 161$) and 1991 ($n = 154$) densities inside 45 ARMs at Santa Rosa and Santa Cruz Islands in the Channel Islands National Park (Davis 1995) were higher than

today (3.6/ARM). If conditions remain unchanged in the south, we may no longer be able to detect recruitment using <100 ARMs. This suggests that adult densities may have declined to the point where we are now observing recruitment overfishing.

In contrast, to the south higher numbers of juvenile abalone (5.30/ARM) were found in northern California from 2001 to 2003 where adult red abalone densities were 8,000/ha on the natural reefs. Similar numbers of juveniles in the north were found in the ARMs as compared with the natural reef (Fig. 3), however too few abalone were observed to make this comparison in the south. Elsewhere higher densities have been found inside artificial habitats than on the natural reef (Hayashi & Yamakawa 1988, DeFreitas 2003). The endangered white abalone (Hobday et al. 2001), the pinto, and threaded abalone (Rogers-Bennett et al. 2002a) were all found in ARMs indicating they are suitable for monitoring even rare species. In the north, flat abalone were regularly observed inside ARMs even though they make up less than 14% of the population (Rogers-Bennett & Pearse 2001). Our results suggest ARMs are a useful tool for monitoring juvenile abundance in an active fishery as well as where populations have declined. The numbers of juveniles within ARMs from healthy stocks in the north (5.3/ARM) can be used as minimum targets for restoration criteria in California.

We examined the abundance of juvenile abalone, some months after settlement as previous studies have done (Sainsbury 1982, Shepherd & Turner 1985, Prince et al. 1987). To assess year class strength, a time series of these data could be collected encompassing a variety of oceanographic conditions including high-frequency environmental fluctuations such as El Niños, as well as low frequency environmental fluctuations such as regime shifts

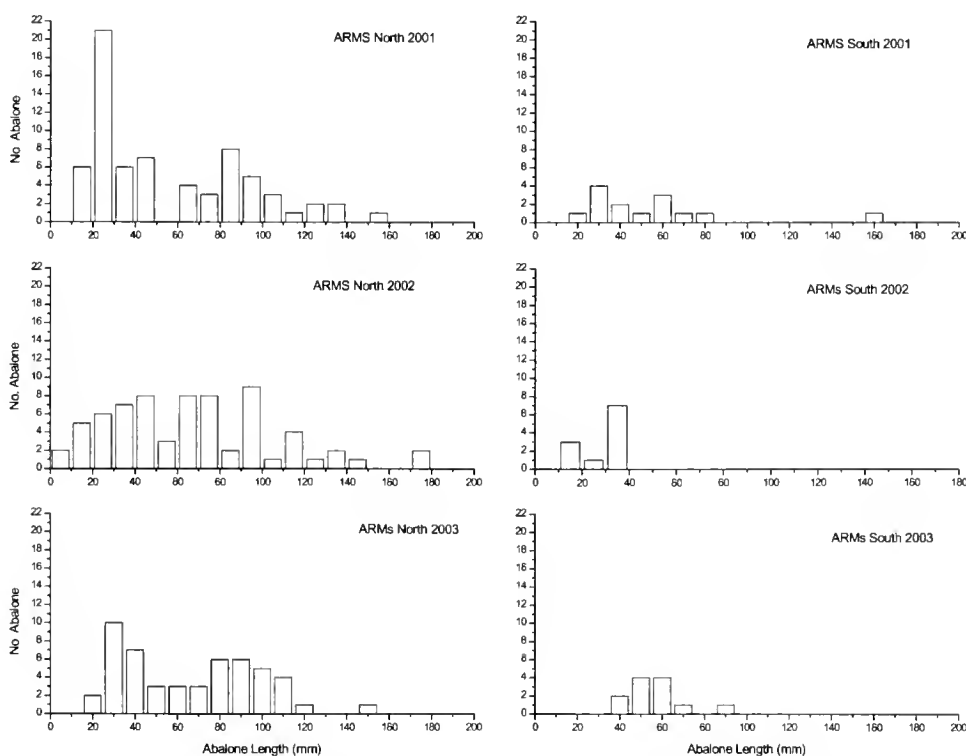

Figure 2. A comparison of the size frequency distributions of abalone *Haliotis* spp. found inside ARMs in southern and northern California in 2001, 2002, and 2003. The top two graphs are the abalone found in the ARMS in southern California and the bottom two graphs are the abalone found in the ARMs in northern California. The length of the abalone in mm is on the X axis and the number of abalone of that size is shown on the Y axis.

No abalone measurements were made on the natural reef in 2003. The top two graphs are abalone found inside the ARMs and the bottom two graphs are abalone found on the natural reef.

(Mantua et al. 1997). Furthermore, recruitment levels could be assessed across a gradient of adult densities, in between the high and low densities that we have examined, to reveal the relationship between stock size and recruitment.

Establishing if there is a relationship between spawners and recruits at the local level is vital for protecting against localized recruitment overfishing. In southern Australia, where the longest time series of stock-recruitment measures exist for abalone (examining 2-y-old juveniles), no clear relationship was found in a reserve population (Shepherd 1990). Experimental adult removals however, demonstrated that there was a positive correlation between local adult density and the number of newly settled abalone (Prince et al. 1988). Either adult spawner density is linked with local recruitment, or larvae from local and distant sources preferentially settle and survive with high densities of adult abalone (Breen 1992). Abalone unlike other invertebrates, such as sea urchins, may have limited larval dispersal (Tegner & Butler 1985, Prince et al. 1987). This suggests restoration programs should not rely on natural larval dispersal to recover distant populations (Tegner 1993). A minimum density threshold (allee effect), has been suggested for abalone (Shepherd & Brown 1993) below which recruitment fails precipitating either local or global extinction (Roberts & Hawkins 1999). Our results in the south support this threshold concept. One mechanism proposed to explain this threshold is the significant drop in fertilization success at low densities despite high fecundities (Babeoek & Keesing 1999). This is relevant not only for management of the recreational red abalone fishery in the north, but also for restoration of endangered and threatened species of abalone in southern California.

In conclusion, recent abalone population surveys (2002) in

southern California indicate that 98% of the remnant pink, green and white abalone populations are comprised of large old adults (CDFG unpubl. data). The absence of large juveniles and small adults from the size frequency distributions suggests that there has been little successful recruitment on these natural reefs in the past decade (except for red abalone at San Miguel Island) (Rogers-Bennett pers. obser.). Densities of pink abalone are low even inside reserves in southern California (Rogers-Bennett et al. 2002b). Today, the white abalone in southern California is at dangerously low population levels and the absence of small adults and juveniles suggest there has been 2 decades of recruitment failure (Hobday et al. 2001, Lafferty et al. 2004). Given the dire state of many abalone populations in southern California today abalone restoration programs cannot delay. We recommend that abalone restoration programs (1) incorporate strategies to assess juvenile recruitment (such as ARMS); (2) determine recruitment levels based on healthy stocks; and (3) use measurable quantitative recovery criteria (Gerber & Hatch 2002).

ACKNOWLEDGMENTS

The authors thank D. Kushner for his assistance with the KFMP ARMs and transect data. The authors also thank all the CDFG and U.C. divers who helped install and census the ARMs along the ever challenging north coast. Special thanks to the CDFG dive program, the office in Fort Bragg, and wildlife protection. Support came from the recreational abalone stamp through the Recreational Abalone Advisory Committee and the California Department of Fish and Game. This manuscript was improved by two anonymous reviewers. Contribution number 2229, Bodega Marine Laboratory, University of California Davis.

EFFECTS OF EXTENSIVE SEEDING ON ABALONE, *HALIOTIS DISCUS DISCUS*, ABUNDANCE ON THE PACIFIC COAST OF BOSO PENINSULA, JAPAN

TOSIATU SIMIZU* AND KANAKO UCHINO

Chiba Prefectural Government, Fisheries Research Center, Japan

ABSTRACT Abalone resources in Chiba Prefecture, the Pacific coast of central Japan, have been severely reduced in recent years. Our investigations have revealed that the density of the mature abalone in this area is 0.019 ind./m², which may be insufficient for successful reproduction. In this study, we investigate the effects of extensive seeding on stock enhancement of abalone, *Haliotis discus discus*. We experimentally released 400,000 juveniles (3.0 cm in shell length, SL) to the research field of 8,000 m² in May 1998 and investigated the growth and stock conditions by SCUBA. The abalone seeds grew up to 10.2 cm SL on average in 3 y and 12.8 cm SL in 4 y, exceeding the legal catch size (12.0 cm) by the Chiba Prefectural Regulation of Fisheries Adjustment, and subsequently commercial catches started in 2002. The catch per unit effort (CPUE) was increased to a great extent from 3 kg/day-boat to 9 kg/day-boat. The inhabited area was considered to be expanded to 100,000 m² based on the catch logs by the local fishermen. As of May, 2002, a production of 57,000 abalones was estimated to be attained by the extensive seeding.

KEY WORDS: seeding, stock enhancement, abalone

INTRODUCTION

Abalone catch used to be 800 t a year in Chiba Prefecture, the Pacific coast of central Japan. The catch has been remarkably decreased to less than 100 t in recent years. Our investigation has revealed that the density of mature abalone is 0.019 ind./m², which may be insufficient for successful reproduction (Shepherd & Brown 1993, Shepherd & Partington 1995, Badcock & Keesing 1999). In this study, we investigate the effects of extensive seeding on stock enhancement of abalone, *Haliotis discus discus*.

METHODS

We experimentally released 400,000 artificial abalone juveniles (3 cm in shell length, SL; 4.3 g) to the research field of 8,000 m² in May 1998 and investigated the growth and density by SCUBA. The juveniles were produced from natural adults collected in the research field and were 1.5 y old at the time of release. The research field is "reefy" seashore (3–5 m in depth) and is one of abalone fishery grounds in Bosu Peninsula.

The released abalone reached the legal catch size, and commercial catches started in May 2002. We analyzed the catch number and location data on the daily catch log recorded by all local fishermen (9 in total). The fishermen dived to catch the abalone with goggles and a bathing suit. It was prohibited for Ama fishermen to use a snorkel tube, fins, wetsuit, and SCUBA gears. The fishing season was from May to August.

The stock size was estimated by the DeLury method, which is based on the regression between CPUE and cumulative catch number. The occurrence rate of released abalone out of the total catch was multiplied to the estimated stock size to obtain the stock size of the released abalone. Released abalone can be easily recognized by greenish color of the shell; however, because the recognition results differed between fishermen and us, we used our results.

The horizontal distribution of the released abalone was estimated with the estimated stock size and the CPUE values calculated for each 50-m transects.

The survival rate of released abalone seeds is supposed to be low within the first 1 mo after releasing and become higher and stable afterwards (Tanaka & Sakamoto 2001). We set the stable natural mortality coefficient to be 0.223/year (Simizu 2000), and the early survival rate was set to be 0.33, which was calculated with estimated stock size and the number of released shells.

The expected catch of released shells in weight and price within 15 y after releasing were evaluated by growth-survival model (Beverton & Holt 1956), and the price values were compared with the expenditure, which is required for seeding. The average fishing mortality values (0.184) was used for the evaluation.

RESULTS AND DISCUSSION

Growth and Maturation

The abalone seeds grew up to 10.2 cm SL on average in 3 y and 12.8 cm SL in 4 y, exceeding the legal catch size (12.0 cm) by the Chiba Prefectural Regulation of Fisheries Adjustment (Fig. 1). Because the size at the time of release (1.5-y-old) was small compared with natural abalone (Simizu 2000, 2001), subsequent growth was also slower. Testes of 4 males (mean SL = 7.3 cm) were in mature stage (Tomita 1968), and ovaries of 4 females (mean SL = 7.5 cm) were in premature stage or mature stage (Tomita 1967) in October 1999 (Fig. 2). We observed that some abalones recaptured in May 2002 and kept in a tank spawned eggs in following November.

Habitation

Our SCUBA investigations revealed that the abalone densities, which were 50 ind./m² at the time of release, were 0.17 to 0.20 ind./m² 1.5–3 y after the release, and 0.45 ind./m² 4 y after the release. According to the analyses based on the catch logs by the local fishermen, the densities were 0.56 ind./m² on average, and the maximum was 1.8 ind./m² 4 y after the release. Higher density values in 4 y rather than in 1.5 y after the release was probably because of the difficulty in finding smaller individuals hiding between rocks. The habitation range expanded to 10,000 m² in May 2002 (i.e., 4 y after the release) shoreward toward shallow areas

with many stones (Fig. 3). This may be because seabed with many stones is more suitable than reefy bottom as a habitat.

The Catch and Production of Abalone Resources by Seeding

Because the seedlings had not been done in the survey fishery ground, occurrence of released abalone was low. However, it increased rapidly to 68% in 2002 (Fig. 4). Increased number of released abalone increased CPUE to a great extent from 3 kg/day-boat to 9 kg/day-boat (Fig. 5).

The number of abalone was greatly reduced from 400,000 to 132,000 in 1 mo after the release in May, 1998, and it became 57,000 in May 2002 (Fig. 6). A part of the abalone with fast growth was caught in 2001 (1,600 individuals), and all individuals recruited to fishing in May 2002. During the fishing season in 2002, 4,500 individuals were caught.

Trial Calculation of Seeding Effects

The overall recapture landing was provisionally calculated to be 31,000 individuals or 10.4 t. Recapture rate was calculated to be 7.8%. Seeding used to be conducted in the survey area from 1968 to 1981, and the recapture rate during this period was estimated to be 8.8% (Sakamoto *et al.* 1986). The average unit price of the abalone is assumed to be 6,200 yen/kg, thus the effect of seeding is calculated to be 65 million yen. The expenditure of seedlings was 19 million yen; therefore, substantial benefit is considerable

even after handling and transportation expenses are subtracted. Continuous field survey is necessary to estimate accurate figures.

As of May, 2002, a production of 57,000 abalones was estimated to be attained by the extensive seeding. The maximum abalone density was estimated to be as much as 1.8 ind./m². These presumption results indicate effective enhancement of abalone production.

GONAD DEVELOPMENT IN SEEDED *HALIOTIS LAEVIGATA*: GROWTH ENVIRONMENT DETERMINES INITIAL REPRODUCTIVE INVESTMENT

LUKE A. MCAVANEY,* ROBERT W. DAY, CAMERON D. DIXON AND SYLVAIN M. HUCHETTE

Zoology Department, University of Melbourne, Victoria, 3010, Australia

ABSTRACT Cultured *Haliotis laevigata* (Donovan), 18 mo old, were tagged and seeded at either high or low densities on boulder reefs (4–6 m depth) at Cape Jervis, South Australia in September 2001. Surveys every 3 mo quantified growth history and a sample was sacrificed in September 2002, prior to the expected spawning season of *H. laevigata* from this area, to measure gonad development. This provided a unique opportunity to investigate the onset of reproductive investment in known age *H. laevigata* in the field. Forty-five percent of sampled abalone had developed gonad tissue by September 2002. Larger individuals were more likely to have initiated gametogenesis and tended to have larger gonads. Gonad development was most closely related to abalone weight in September 2002 and was also strongly correlated with length and early growth rate. A significant proportion of abalone migrated from cryptic positions within boulder habitats into more exposed adult habitat at the outer edge of reefs between April and June. Abalone that had emerged to adult habitat were significantly more likely to be mature than cryptic individuals. The overall proportion of abalone with developing gonads differed significantly between densities. This seems to be an indirect effect, arising because abalone at low density grew faster than those at high density. The onset of sexual maturation in *H. laevigata* was thus partly dependent on density and site characteristics, which probably reflect the relative availability and quality of food. The results suggest that onset of sexual maturity in *H. laevigata* can advance under conditions of fast growth. As sampled gonads contained ripe gametes and maturity appears to be related to growth rate, fast growing abalone may reproduce ≥ 1 y before smaller juveniles in the same cohort.

KEY WORDS: gonad development, growth, maturity, density, *Haliotis laevigata*

INTRODUCTION

Abalone exhibit wide variation in growth rate (reviewed in Day & Fleming 1992) and size at maturity (McShane & Naylor 1995a). Much of this variation is likely due to inherent variability in the environment, but other aspects may explain these patterns. Life history theory predicts that most organisms will mature at neither a fixed age nor at a fixed size, but along an age–size trajectory according to environmental constraints such that reproductive fitness is optimized (Stearns & Koella 1986). For abalone, factors such as density, previous growth history, and food availability (or quality) may promote large differences in growth rate and the timing of maturation. How these factors specifically relate to gonad development, however, remains poorly understood. The difficulty of monitoring cryptic juveniles in the field (McShane & Smith 1988) has largely limited research to laboratory studies.

Intraspecific competition in abalone, which are dependent on a limited supply of drift algae as food (Shepherd 1973), might be expected to result in reduced growth and/or fecundity at higher densities. Laboratory and aquaculture studies have shown that high stocking densities can have strong negative effects on the growth of juvenile abalone (Mgaya & Mercer 1995, Capinpin et al. 1999, Huchette et al. 2003). A field experiment involving adult *H. iris* in New Zealand showed that reproductive investment (measured as dry gonad weight) was independent of density (McShane & Naylor 1995b). Douros (1985) found that size-specific reproductive investment in *H. cracherodii* was increased at a site where density was reduced, relative to a control site. Density effects on reproduction have been shown in several terrestrial molluscs (Carter & Ashdown 1984, Baur & Baur 1992), but there seem to be no studies of these effects on the initial reproductive investment of animals as they approach maturity.

Strong size-dependent mortality rates in juvenile abalone (Shepherd & Breen 1992, Shepherd 1998) may shape selective

pressure such that the onset of maturity is linked with the attainment of a threshold size (McShane & Naylor 1995a, Worthington & Andrew 1997). Nash (1990, 1992), however, concluded that sexual maturity is determined by reaching a certain age, rather than size, in *H. rubra*. This is also argued for other abalone species (Shepherd & Laws 1974, Shepherd et al. 1991) and has strong theoretical support (Stearns & Koella 1986). There is some evidence that the age of first maturity in abalone may be a plastic trait that is influenced by growth rate (McShane & Naylor 1995a) but this is yet to be demonstrated in a known-age population.

This field study investigated the effect of growth history (i.e., previous growth) and local density on the timing and degree of maturation in seeded abalone reaching first maturity. Practical difficulties associated with relying on natural recruitment in the field were avoided by using tagged, cultured juveniles that were all the same age.

MATERIALS AND METHODS

Experimental Design

This study was carried out near Cape Jervis, South Australia (138° 06'E, 35° 36'S) between September 2001 and September 2002. Eighteen-month-old cultured abalone from Kangaroo Island Abalone hatchery with mean shell length 28 mm (SE = 3 mm) were tagged with polyethylene tags (Hallprint, South Australia). Abalone were allowed to recover from the tagging procedure for 5 days before being transported to the study area in ice boxes filled with damp hessian sacks.

Four sites at depths of 4–6 m were selected according to their proximity to seagrass habitat (*Amphibolis* and *Posidonia* spp.) and the presence of adult *H. laevigata* in low densities. Sites were semiexposed areas of flat sand substratum surrounded by seagrass with high epiphyte loads and were situated 20–30 m from natural abalone reefs. At each site, six 6 m² rectangular experimental reefs were assembled, arranged in a 12 m × 9 m grid, each 3 m apart. Each experimental reef consisted of two layers of medium-sized

*Corresponding author. E-mail: l.mcavaney@pgrad.unimelb.edu.au

boulders (20–40 cm across) collected from the surrounding area with intact natural faunal assemblages associated with them. Six stocking densities (9, 14, 18, 24, 30, and 45 abalone per m²) were randomly allocated among the experimental reefs at each site. The two highest densities at each site were designated as high-density treatments and the remaining four densities were designated as low-density treatments. Tagged abalone were seeded onto experimental reefs in open bags of plastic mesh from which they could easily disperse. The methods used during the seeding process are dealt with more fully in Dixon et al. (2005).

At 3, 6, 9, and 12 mo postseeding, surveys were made to quantify growth and mortality. The reefs were progressively dismantled and reassembled by divers, and an exhaustive search undertaken to find all abalone from each reef. The tag number and length (to the nearest 1 mm) were recorded *in situ*, to calculate growth over each 3-mo period (growth increment). The position of each recovered abalone was also recorded to determine if the individual was more likely to have been exposed to higher flow rates on the tops of rocks or more food at the outer edges of reefs. During surveys, we chose not to remove predators from experimental sites as we sought to create near-natural conditions.

In early September 2002 (Austral spring), a number of abalone that had moved off reefs at one site were collected to determine an appropriate sampling regimen. These animals were removed from the shell and visually assessed for the presence or absence of gonad tissue. In this pilot study, the minimum size of abalone with differentiated gonad was ~60 mm. Following the results of the pilot study, we visited each site for sampling in late September 2002, just before spawning is expected in *H. laevigata* from this area (Shepherd 1992). We targeted our collection to recover 30 individuals from high and low-density reefs. After an exhaustive search of each reef, we sampled animals that were larger than 60 mm and represented a range of sizes present at each site. An additional 14 abalone >60 mm were randomly collected from high and low-density reefs at one site for histologic examination of gonad tissue.

Following sampling, abalone were weighed (drained live-weight) to the nearest 0.1 g and shell length was measured to the nearest 0.2 mm. Following measurement, the soft tissues were shucked and photographed in dorsal view using a SLR camera with a macro lens. The photographs were used to score a visual gonad index (VGI) based on the progression of the early stages of gonad development following the criteria in Table 1. In developing a scoring system for the VGI, it was important to include a wide range of possible scores to allow good estimates of the error variance in the data. The VGI differs from other visual indices in this respect, since these systems are based on much coarser (4 or 5 point) scales (e.g. Kikuchi & Uki 1975, Ault 1986). A fine scale VGI was also better able to distinguish between samples at the early stages of gonad development.

Histologic samples of gonad tissue were stained with Mallory Triple Stain and examined under a high power microscope for the presence of well-developed gametes (after Giorgi & DeMartini 1977).

Statistical Analyses

The visual gonad index used to quantify gonad development in maturing abalone cannot be considered an interval scale, and so could not be used as a dependent variable in statistical parametric analyses. To study the relationships between length, growth rate,

TABLE 1.
Criteria for assessment of the visual gonad index (VGI) in *H. laevigata* from Cape Jervis, South Australia.

VGI	Criteria
0	No gonad visible, immature.
1	Gonad membrane apparent, beginnings of gonad on under-side of conical appendage.
2	Some gonad membrane on proximal side of stomach and visceral spire.
3	Gonad tissue apparent on conical appendage.
4	Gonad tissue apparent on visceral spire.
5	Gonad tissue thickening around visceral spire and proximal side of stomach.
6	Gonad tissue thickening on conical appendage.
7	Thick gonad tissue on proximal side of stomach.
8	Approximately 50% of visceral spire covered in gonad tissue.
9	Visceral spire covered in gonad tissue.
10	Approximately 50% of conical appendage covered in gonad tissue.
11	Thick gonad tissue covering entire visceral spire, stomach and conical appendage.

and gonad development, simple regressions were performed against VGI. Although there is no reason to expect a linear relationship against the index scale in these analyses, the regressions measure the strength of a trend.

Because a large proportion of sampled abalone had a VGI of zero, parametric analyses of these data were not appropriate. To study the effects of density and site on gonad development, abalone were grouped by size. The proportion of abalone in each group with a VGI > 0 and the mean length of the group were measured as new variables. The proportion of mature abalone per group with some gonad could then be analyzed as the dependent variable in an analysis of covariance with mean length of the group as the covariate and treatment and site as factors. Similarly, an analysis of variance was performed with the mean size of the group as the response variable. One site was excluded from these analyses because only one individual at that site had developed gonad.

$P < 0.05$ was regarded as significant in all statistical tests (0.001, highly significant).

RESULTS

The mean density of abalone on experimental reefs a year after release (September 2002 *in situ* survey) was 16 abalone per m² at high density (range 15–17) and 7 abalone per m² at low density (range 5–11). A *t*-test showed that these densities had remained significantly different after 1 y ($t_7 = 4.708$, $P = 0.002$). Table 2 shows the size distribution of our overall sample from high and low-density reefs. Overall, 45% of the individuals sampled after 1 y had developed visible gonad tissue (48% at low-density, 40% at high-density). The mean length and weight of these was 74.1 mm (SE = 4.3 mm) and 47.5 g (SE = 8.8 g) respectively.

Examination of the 14 abalone collected for histology showed that those with discernable gonad development had gametes present in all cases and that females with a VGI > 4 had eggs in advanced stages of vitellogenesis (large, rounded oocytes, >100 µm). All male gonads appeared to contain viable sperm, spermatozoa being densely packed in the lumen of tubules.

TABLE 2.

Size distribution of *H. laevigata* sampled for gonad analysis in September, 2002.

Density	Size Class (mm)					Mean Size (mm)
	60-65	65-70	70-75	75-80	80+	
HIGH	9	41	40	12	1	70.2
LOW	1	36	53	40	11	72.4

A regression of length at capture after 1 y against VGI gave a significant positive relationship ($r^2 = 0.196$, $n = 244$, slope = 0.443, $P < 0.001$; Fig. 1). Thus abalone with a higher VGI tended to be larger and, conversely, those that had not developed gonad or had small gonads tended to be smaller. Regressions were performed to relate growth history and size of these abalone to gonad development (Table 3). Density was not considered in these models.

Over all size classes, more abalone were mature at low density than at high density (48% and 40% respectively, Fig. 2). Animals at high density, however, formed a larger percentage of mature animals in the medium size classes (e.g. up to 13% more by the 72-mm class). In the analysis of covariance (described in the Methods section), density treatment showed no significant effect on gonad development, but the covariate of length was highly significant (ANCOVA: $F_{1,23} = 38.195$, $P < 0.001$). Furthermore, density had a significant effect on the mean size of abalone across all sites (2-way ANOVA: $F_{1,24} = 6.774$, $P = 0.016$).

There was a marked increase at all sites in the percentage of abalone that were found on the edge of experimental reefs (i.e. adjacent to sand and seagrass) between March and June (Fig. 3). Abalone on the edge of the reef in June were also more likely to have developed gonad by September (2-way table: $\chi_1^2 = 5.881$; $P = 0.015$). Being on the edge of the reef at other survey times did

not correlate with gonad development. Abalone found on the tops of rocks during the study were also no more likely to develop gonad than other animals. A smaller proportion of individuals were on the edge of reefs at high density compared with low-density reefs (Fig. 3) and this difference was significant in June (2-way table: $\chi_1^2 = 5.14$, $P = 0.023$).

DISCUSSION

This study was carried out using 18-mo-old cultured juveniles (28.1 mm mean length) that were seeded into a near-natural field environment. Growth rates for these animals while in the hatchery (i.e. prior to release) were very similar to those reported for wild

Figure 2. Line graph showing the cumulative percentage of *H. laevigata* with gonad tissue for each density treatment. Data from all sites are pooled. Solid line = High density; Dashed line = Low density.

juveniles of the same age at West Island (a nearby site with similar characteristics). Shepherd (1988) showed that wild juveniles consistently reached 25–29 mm in their first 18 mo in a study of 5 separate cohorts at West Island, whereas Shepherd and Hearn (1983) recorded growth rates of up to 39 mm in the first year at the same location. The experimental reefs were assembled from natural substrates complete with predators and interspecific competitors. Treatment densities, in terms of the number of abalone per area of suitable habitat, may also be compared with densities of wild adult *H. laevigata* found by Dixon and Day. The growth rates we observed in the field for our study (~40 mm per year) were comparable to those seen in wild juveniles of a similar size (Shepherd & Hearn 1983, 33 mm per year; Shepherd 1992, 43.4 mm per year). The mortality rates recorded in our experiment (see Dixon et al. 2005) were also similar to those found in wild juvenile populations (Shepherd 1998). With all of these considerations, we are confident that our results provide valuable and relevant information for wild stocks.

The size of abalone, in terms of length or weight, seems to be the most important determinant of maturation in *H. laevigata*. Considering the known age of all abalone released into the field (30 mo in September 2002), we can conclude that, in a maturing population, larger abalone would become reproductive one or more years before smaller abalone of the same age. This is an important finding in the light of other studies that suggest maturity in wild abalone is genetically determined on reaching a certain age (Shepherd & Laws 1974, Prince et al. 1988, Nash 1990, Shepherd et al. 1991, Nash 1992). Because larger abalone were the faster growing individuals over the year, our results strongly suggest that there is significant plasticity in the age at which *H. laevigata* become mature and that this age varies with growth rate.

Abalone in this experiment were of a similar size when re-

leased, so differences in the growth rate of individuals are responsible for whether these abalone matured in 2002 and their degree of gonad development. Significantly, juvenile somatic growth during the first 3 mo of the study was most important in determining both final length and the amount of gonad developed by September, whereas growth in subsequent periods was not strongly correlated to the VGI. The strong influence of initial growth rate on subsequent gonad development might be attributable to stress induced during seeding (Schiel 1993), such that less stressed individuals that grew well immediately following release had a significant advantage over other abalone. It is possible, therefore, that growth and the timing of maturation in abalone will be sensitive to other environmental stresses.

Another intriguing possibility is that seasonal growth (i.e. in Spring) when food is more abundant is especially important for maturing abalone. Another hypothesis is that individual juvenile abalone may have differing inherent growth rate potentials by virtue of some aspect of body condition. We were unable to separate these hypotheses in our experiment, but suggest that stress is likely the dominating influence.

It remains to be determined whether early growth performance in a natural cohort of juveniles would be a strong determinant of the timing of maturation. It is believed, however, that nutritive differences very early in life will shape growth and maturity patterns as animals grow (Stearns 1992). Indeed, early growth in abalone is often associated with later growth performances in the hatchery (Huchette 2003).

Abalone at high-density grew more slowly than those at low density, as reported in aquaculture studies (Mgaya & Mercer 1995, Capinpin et al. 1999, Huchette et al. 2003) and in the field (Dixon & Day 2004). Density also seems to affect the timing and degree of gonad development in *H. laevigata*. Abalone at high-density seemed to initiate gonad development at smaller sizes than those at low-density (Fig. 2). This tendency amongst slow growing populations of organisms is well documented in life history theory (Stearns & Koella 1986) but this study constitutes direct evidence of this in abalone.

The finding that, overall, a higher percentage of abalone from low density reefs were mature is clearly an indirect effect, related to the size of abalone at low density. That is, abalone at low density grew faster. The indirect effect of density on maturation is important because in years of low recruitment to an abalone population, compensatory increases in the growth of young individuals are likely (if levels of interspecific competition are the same) to increase the average individual egg production from that cohort.

It has been suggested that abalone populations with fast growth tend to mature at a younger age than slower growing populations (Wells & Mulvey 1995, Shepherd & Triantafillos 1997). Our results correspond with this since large, faster growing *H. laevigata* began to show signs of maturity at least 1 y before slower growing individuals. This suggests that the timing of maturation in abalone is a plastic trait in response to growth rate and that maturation is not genetically determined to commence at a given age. Empirical evidence for this plasticity was provided by a study on *H. iris* by McShane and Naylor (1995a). Based on length-at-age data, McShane and Naylor found that abalone that were exposed to higher flow rates (and hence more food) near headlands tended to grow faster, and mature earlier, than those in sheltered bays. Our study is the first to demonstrate plasticity in the timing of maturation within a local abalone population and our results are consistent with findings in other marine invertebrates (Thompson 1979, Franz 1996) and in fish (Stearns & Crandall 1984, Reznick 1990).

Anecdotal evidence from aquaculture studies suggests that small *H. laevigata* (50–60 mm) can be successfully induced to spawn in the hatchery (John Hall, pers. comm.). This may represent a size limit in *H. laevigata*, below which individuals are physiologically incapable of spawning. Histologic examination of gonad tissue from Cape Jervis abalone (all of which were >60 mm) suggested that larger individuals with more gonad would be capable of spawning but, because of their relatively small size, gamete production would be low.

If these abalone gain one or more extra spawning seasons due to their earlier maturation, this could be significant in the management of the fishery because the reproductive output of a cohort will vary considerably as individuals approach sexual maturity. It is possible that larger abalone at Cape Jervis actually spawned in 2002. The fact that these abalone had already developed gonads at 30 mo, and were also the fastest growing individuals in the cohort, might allow them to produce larger gonads in future spawning seasons than other abalone. It is also possible that abalone with faster early growth may reach a higher asymptotic length (and hence higher reproductive capacity, Stearns 1992), but our data cannot test this hypothesis. In either case, abalone that mature earlier have a substantial reproductive advantage over slower growing abalone that have remained small (Roff 2002).

Prince et al. (1988) and Nash (1992) suggested that the commencement of maturation and end of exclusively somatic growth also coincided with the emergence of *H. rubra* to less cryptic positions on rocks, characteristic of adult habitat. The results for *H. laevigata* at Cape Jervis correspond with this because many of the abalone that developed gonad were found to be on the edge of plots in June where they sat on rocks bordered by sand and seagrass. This position would give abalone better access to drift algae (Shepherd 1973) and is characteristic of adult *H. laevigata* habitat. It is important to note that in our experiment, densities of adult *H. laevigata* were low on experimental reefs such that adult habitat was largely vacant. In populations where adult densities are higher, juveniles may face stronger competition for positions on the edge of reefs.

The emergence of large numbers of abalone to the edge of plots between March and June seems to precede the development of gonad tissue, which is believed to take place between June and September (Shepherd & Laws 1974, Shepherd & Hearn 1983). This may reflect a delay between when more food becomes available and the energetic allocation of resources to growth or reproduction (Day & Fleming 1992, Donovan & Carefoot 1998).

Abalone that were on the edge of reefs in June would have access to more abundant food and were subsequently likely to have developed gonad. This suggests that the amount or quality of food available to juvenile abalone may be important in the initiation of gonad development. Nutrition is known to play an important role in the timing of maturation and is strongly correlated with growth rate in other invertebrates (Lucas & Lawes 1998, Boyd et al. 1986) and in fish (Reznick 1990). Thus differences in growth rate and maturation between high and low-density abalone presumably reflect the more basic difference of increased nutrition.

Across many taxa (including humans), poorly nourished individuals mature much later than well-fed individuals (Stearns & Koella 1986). Our study shows that this is also true for abalone, because animals with greater access to food resources (e.g. those at lower experimental density and/or residing on the edge of reefs) were likely to mature in 2002 whereas abalone with poor access to food would likely not mature for another year.

The age at first maturity in *H. laevigata* seems to be a highly plastic trait in response to different growth rates and/or nutrition levels. The results of our study indicate that the onset of maturation is not fixed at a certain age within a population but can be advanced under conditions of fast growth.

ABALONE RESOURCE DECLINE AND A RECOVERY ATTEMPT IN CHIBA PREFECTURE, JAPAN

KANAKO UCHINO,* TOSIATU SIMIZU, TANE0 TANAKA, AND TERUKAZU SHIBATA

Chiba Prefectural Government, Fisheries Research Center

ABSTRACT Landings of abalone (*H. discus*, *H. gigantea*, and *H. madaka*) in Chiba Prefecture, Japan exceeded 700 t in 1966 and fluctuated between 600–800 t until 1978. The landings started to decline in 1979 and reduced to less than 100 t in 1997. Although landing of *H. discus* has been slightly increased since 2000, that of *H. gigantea* abalone is still decreasing. We analyzed the data of investigations on decline in abalone landings and have come up with “environment theory”, “over-fishing theory” and “disease theory.” In the environment theory various factors were considered, such as biomass decrease of purple sea urchin; which is used as a shelter by juvenile abalone, sedimentation flux increase, withering of seashore (soyake), oceanic dynamic change, predation damage, coastline development, and endocrine disruptors, of which the sedimentation increase was thought to be the most influential factor. In the over-fishing theory, decrease in the number of reproductive adults due to reinforcement of the fishing intensity was considered to reduce the fertilization success and caused the decline in recruitment. The disease theory was found to be not applicable because virus infection of seeds has not been reported in Chiba Prefecture. To solve the problems related to decrease in adult population number, various research approaches are possible: development of techniques to create suitable reproduction habitat, long term observation of reproductive conditions in a perpetual observation area, improvement of seed transportation and release methods, and development of fishing ground construction technology. We have been conducting research on the effects of leaving the fishing ground fallow for 5 y, and we are also investigating the amount of resources in different developmental stages. The present study summarizes the abalone landing decline factors in Chiba Prefecture and describes the present status of our research.

KEY WORDS: fishing intensity, recovery, abalone, *Haliotis*

INTRODUCTION

In order for Chiba Prefecture to work on the investigation and the measure against production increase of abalone resources, the “abalone resource recovery project,” which consists of administration, test research, and fisheries extension section was established in 1998. To clarify the causes of resource reduction, environmental theory; over-fishing theory; and disease theory were built and examined (Simizu & Tanaka 2001).

ENVIRONMENTAL THEORY

Biomass Decrease of Purple Sea Urchin

Although juveniles are considered to hide under the prickly of purple sea urchin to escape from predator (Kojima 1974, Kojima 1981, Tanaka & Tanaka 1982), purple sea urchin is not necessarily distributed thoroughly in Chiba Prefecture (Anonymous 1980, Anonymous 1981), and abalone juveniles were observed to move out from underneath the spines of purple sea urchin in approach of eight armed starfishes (*Coscinasterias acutispina*). Therefore, decrease of purple sea urchin may not be a major reduction factor (Tanaka 2001).

Sedimentation Flux Increase

There is a report that sedimentation flux influences survival of abalone larvae and juvenile (Yamada & Kamimura 1973, Sakamoto 1979, Sakamoto & Nanba 1980). Growth and survival rate of early juveniles are known to be better in filtered sea water.

Withering of Seashore

Seashore withering is reported to deteriorate food conditions of abalone, causing malnutrition and decline in abalone resources

(Kawajiri et al. 1981, Tanaka & Tanaka 1986). There is a report that production of food seaweed influences survival of *H. discus hannai* (Sakai 1962). However, in the Hamanamekawa and Kawaguchi area where the abalone fishery is performed, flora and the amount of sea oak and sea trumpet, which are the food items of abalone, did not differ between 1978 and 1998 (Tanaka & Simizu 2000).

Ocean Dynamic Change

In *H. discus hannai*, water temperature decrease by cold Oyashio current is one of causes of stock size decline (Shibuya 1984). The Chiba coast is under influence of warm Kuroshio cur-

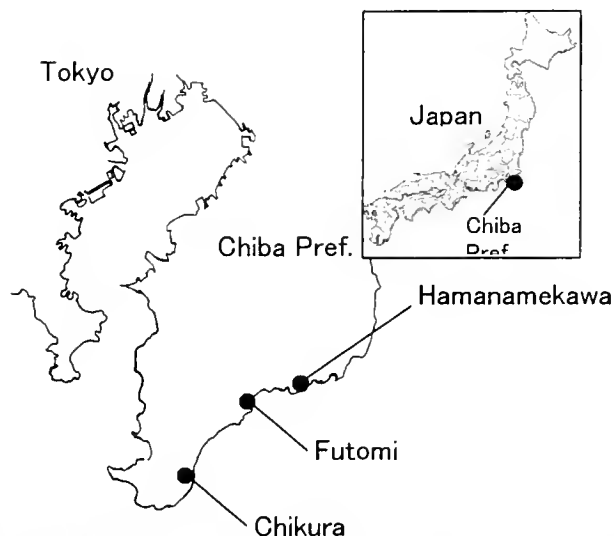

Figure 1. Map of Chiba Prefecture with abalone research location in this study.

*Corresponding author. E-mail: k.uchn2@mc.pref.chiba.jp

Figure 2. Trend of abalone catches from 1960 to 2001 in Chiba Prefecture. The catches started to decline in 1979 and reduced to less than 100 t in 1997. Although catches of *H. discus* has been slightly increased since 2000, that of *H. gigantea* abalone is still decreasing. *H. diversicolor aquatilis* is included in total catch.

rent. Although winter water temperature has been rising slightly since 1986, abalone catch has begun to decrease since 1980 in Chikura areas (Tanaka & Simizu 2000). Thus, on the Chiba coast, water temperature may not be a reduction factor because ocean dynamic change and resource change do not synchronize.

Predation Damage

Octopus, crabs, star fish, snails, and fishes are known predators of abalone (Kojima 1981, Yamakawa 1990, Seimura et al. 1993, Anonymous 1976). However, detailed data of predation damage of abalone are not available. No correlation is found between landings of octopus and abalone (Simizu & Tanaka 2001). This may indicate minor importance of predation on abalone stock, but further studies are required.

Coastline Development

There has been no large scale coastal development in Chiba. Although there supposed to be some local fishery loss by the outflow of earth and sand, damages has been relatively minor.

Endocrine Disruptors

Abnormalities in the gonads of abalone, which are known to be caused by endocrine disruptors, may reduce reproductive activity of abalone (Horiguchi & Shiraishi 1999). However, histologic abnormalities have not been observed in *H. discus* and a *H. gigantea* from Kawaguchi area (Simizu & Tanaka 2001).

OVER-FISHING THEORY

There are reports that describe abalone resource decline due to reinforcement of fishing intensity (Anonymous, 1984, Nonaka 1987, Tachiyama et al. 1998, Horii 1998). In Chiba Prefecture, the possibility that introducing wet suit to diving fishery and/or other elements caused the over-fishing cannot be denied.

The habitat density of 1-y-old abalone was remarkably decreased in 1989 as compared with 1978 (Tanaka & Simizu 2000), indicating the decrease of new recruitment. In Australian greenlip abalone (*Haliotis laevisgata*), high density of broodstock is known to be indispensable for fertilization success (Babcock & Keesing 1999). Decrease in the number of reproductive adults due to rein-

forcement of the fishing intensity was considered to reduce fertilization success and caused the decline in recruitment.

DISEASE THEORY

Although wild abalone may die of virus infection passed on by infected artificial seeds, no virus infection has been reported in the process of the seed production in Chiba Prefecture. Therefore, virus infection does not seem to be major reduction factor of abalone resources.

In summary, the main causes of the abalone resource reduction in Chiba Prefecture seem to be related to over-fishing and we took a measure against recovery based on this conclusion.

Solution for Resource Recovery

Improvement of Abalone Seed Release Method

The recovery rate of the released seeds in Chiba Prefecture is estimated to be 8.8% (Sakamoto et al. 1986). By improving the release method, the survival rate, and therefore recovery rate, may be increased.

The survival rate of abalone seeds can be maximized by the use of a release basket (Fig. 3) (Nishima & Ito 1989, Tanaka & Sakamoto 2001). To date, divers have released abalone by hand in Chiba Prefecture. However handling can damage the seeds. The introduction of a release basket can make transporting and releasing of seeds more efficient. A study of this method was performed to test its effects. The release basket, which is used for *H. discus hannai* release in Iwate Prefecture (Anonymous, 1990), can accommodate about 1500 individuals of seeds (~3-cm SL). The examination was carried out in a developed area with about 200 concrete boards (60 cm × 60 cm) in Hamanamekawa area in November 2001.

Effect of the release basket was examined. The use of the release basket increased the recapture rate of *H. gigantea*, whereas the effects were not clear in *H. discus* (Table1). To mitigate the predator damage of released seeds, water temperature should be low. Use of the release basket, which can make it possible to carry out the release without diving in the winter, may be effective.

Figure 3. Release basket, a concrete slab with slats to fit PVC panels to which abalone juveniles are attached.

TABLE 1.
Comparison of recovery rates between two release basket and diving, in *H. discus* and *H. gigantea*.

Method	Species	At Release Nov. 7, 2001			At Recapture Dec. 4, 2001			
		N	Shell Length (mean \pm SD mm)	Weight (g)	N	Recapture/rate (%)	Shell Length (mean \pm SD mm)	Weight (g)
Release basket		1000	29.8 \pm 1.4	3.7 \pm 0.5	332	33.2	30.4 \pm 1.7	3.6 \pm 0.8
Diving	<i>H. discus</i>	996	29.8 \pm 1.4	3.7 \pm 0.5	354	35.5	30.2 \pm 1.6	3.7 \pm 0.6
Release basket		990	27.8 \pm 1.4	2.8 \pm 0.5	622	62.8	28.9 \pm 1.6	2.8 \pm 0.5
Diving	<i>H. gigantea</i>	959	27.8 \pm 1.4	2.8 \pm 0.5	486	50.7	29.0 \pm 1.8	3.0 \pm 0.6

Development of Suitable Reproduction Habitat

We have been conducting research on the effects of catching abalone every 3 y. One research area 1,000 m², and was developed with about 1,500 sheets of the concrete plates (80 \times 60 \times 10 cm). About 20,000 *H. discus* seeds were released in one area, and the recovery rate was examined after 3 y. Three sets of areas established and "catch rotation during 3 years" is carried out. The amount of recoveries been 300–400 kg per one area on average (Table 2). 700 kg maximum, which is about 2,000 individuals. In an average fishery ground, the benefit of seeding greatly exceeds the cost. This type of catch rotation fishery can expect not only increased recovery of released abalone but it is also functions in the maintenance of high parents density.

Early Ecology of Abalones in Chiba Coast

To attain suitable and effective resource control and enhancement, investigation of resource change mechanisms is indispensable.

The occurrence of planktonic larvae Tidal the flow was investigated, and abalone larvae were collected using the Kitahara plankton net in Ftomj area in 1979 and 1980. The spawning season of abalone was considered to start in late October and end in February, and it became clear that spawning is induced by low atmospheric pressure and rapid water temperature changes. Eggs and larvae were found to be accumulated in the whirlpool region (Tanaka & Ishida 1986). To compare with the past conditions, larvae were collected by the Kitahara plankton net in 2001 and 2002 (Table 3). The densities of *H. discus* and a *H. gigantea* were

0.4 ind./m⁻² and 0.5 ind./m⁻² respectively in 1987 and were 0.01 ind./m⁻² and 0.02 ind./m⁻² in 1998. Despite the fact that there were larger amount of resources 20 y ago, the numbers of larvae collections of the larvae in 2001 and 1980 were in the same level. The occurrence of larvae is a key factor in understanding abalone stocks, yet it is the most elusive. It is necessary to carry out studies on methodology.

The occurrence of postlarvae Occurrence of postlarvae of abalone has been investigated since 1977. We collect natural stones and concrete boards (20 \times 20 \times 2 cm) to extract the juveniles at least once a week in the Kawaguchi area from late October to December, which is the breeding season of abalone. The number of annual accumulation of postlarvae (m⁻²) was the highest in 1977 (i.e., 277) and gradually decreased thereafter to 0–7 in the 1990s (Tanaka & Kasai 2000). This trend seems to be in parallel with the trend of abalone stock abundance: systematic accumulation of knowledge of ecology and methodology is necessary.

CONCLUSION

For abalone stock enhancement, improvement in the survival and recovery rates after the release is raised as a short-term objective, and it is necessary to steadily advance and spread the technologies introduced in this study. Moreover, because the current status of fisheries will not fall to growth-over-fishing if the present legal size (i.e., 12 cm) of capture is kept (Simizu 2000), appropriate measures such as enlightenment on fisheries association consciousness, poaching prevention and shell length restric-

GROWTH RESPONSES IN EMERGENT GREENLIP ABALONE TO DENSITY REDUCTIONS AND TRANSLOCATIONS

CAMERON D. DIXON AND ROBERT W. DAY

Zoology Department, The University of Melbourne, Victoria

ABSTRACT Growth of “stunted” greenlip abalone in areas with low maximum sizes was enhanced over 6 mo by reducing their natural density and by translocation to habitats supporting faster growing abalone. Density reductions significantly increased growth relative to controls, apparently without altering the asymptotic length. Stunted abalone showed a consistent and similar pattern of enhanced growth when translocated to two sites where abalone characteristically grow faster and to larger sizes. When compared with slow growth control abalone, the response of translocated abalone varied with initial length in the same manner as in the experiment where density was reduced. When compared with fast growth controls, translocated abalone had similar trends in growth increment versus size, yet all size categories grew consistently less. Statistical comparisons cannot be made between density-reduced and translocated abalone because abalone in the density reduction experiments were tagged *in situ*, whereas translocated abalone were tagged aboard a research vessel. The fact that reduced density and better quality habitat positively influence growth patterns of greenlip abalone, producing the same short-term response, suggests that food availability may limit the growth of stunted populations. The asymptotic length, which appeared unaffected in both experiments, may be determined by long-term conditions, or perhaps by conditions during the onset of maturity.

KEY WORDS: abalone, *Haliotis laevigata*, density-dependence, growth, density-reduction, translocation

INTRODUCTION

An understanding of density dependent processes is essential to fisheries management, particularly compensatory effects that can offset natural or fishing-induced reductions in biomass (Rose et al. 2001). Several studies have reported interspecific competition that resulted in density dependent changes in growth rate (Kamermans et al. 1992, Brazeiro & Defeo 1999, Barki et al. 2001, Tafman & Keough 2001, Vromant et al. 2002), but experimental manipulations of density to determine effects of intraspecific competition in the wild are often logistically difficult, particularly for subtidal species.

Stoner (1989) showed that growth of the queen conch, *Strombus gigas*, was significantly different at densities two and four times those observed in the wild and he suggested that this result was food related. Marshall and Keough (1994) also provided evidence of density-limited growth for the limpet, *Cellana tramoserica*. Abalone, like conch and limpets, can often be found in high-density aggregations (Shepherd 1986, McShane 1995, Officer et al. 2001), and because they feed on drift algae it is reasonable to postulate that abalone density, as a result of intraspecific competition for food, may affect growth.

Most abalone research investigating density dependent growth has been restricted to aquaculture experiments (Hum et al. 1995, Mgaya & Mercer 1995, Capinpin Jr. et al. 1999, Huchette et al. 2003), and in each case growth was negatively correlated with density. In contrast to these results, McShane and Naylor (1995a) reported density independent growth of *Haliotis iris* from field experiments in New Zealand. In their experiment McShane and Naylor artificially increased densities within enclosures, using natural densities for the controls. They acknowledged that a more realistic experiment to test density effects would be achieved with a reduction, rather than increase, in density. “Stunted” populations of abalone (McShane et al. 1994, Wells & Mulvay 1995), where few individuals will ever grow to the legal minimum length and therefore most will remain unfished, provide a unique opportunity to conduct such manipulative experiments in a population at natural density.

Translocation of abalone to habitats with greater food abundance or quality has been shown to increase growth rate. Emmett and Jamieson (1989) transplanted stunted *H. kantschikana* to better quality habitats and obtained growth rates twice those of control populations. McShane and Naylor (1995b) also observed significant increases in growth rate when *H. iris* were translocated from bay to headland habitats. A review by Day and Fleming (1992) concluded that variation in abalone growth was primarily due to the quality and quantity of algal food available. Assuming that density affects food availability per individual, a reduction in density could be expected to invoke a similar growth response as translocation of abalone to better quality habitats.

Our experiment, conducted over a 6-mo period, studied the effect of density reductions at three sites with stunted abalone at Tiparra reef, South Australia. Abalone removed from two of these sites were translocated to locations with fast growing abalone, and controls of both stunted abalone and fast growing abalone were tagged to determine the effect of changing habitat on growth.

METHODS

During March and April 2002, 2,940 greenlip abalone were tagged at five sites on Tiparra Reef, South Australia (Fig. 1), using rivet tags inserted into a respiratory pore of the shell (Prince 1991). Tagged abalone (1,873) were recaptured and measured for shell growth during September 2002.

The experiment to determine the effect of density on shell growth was established at three sites where abalone grew to small maximum lengths. We assumed that growth at these sites would be slow, and the results confirm this. These sites were within a kilometer of each other, separated by areas of unsuitable habitat. Within each site two adjacent areas were marked out and measured, and abalone were tagged *in situ* in each area. We did not anticipate extensive movements during these experiments because Shepherd (1973) observed that movements were minimal over long periods of time at a site near to the Tiparra Lighthouse. We therefore established the control areas only 10 m from treatment areas to minimize differences between them. In control areas all emergent abalone were tagged, and in treatment areas every third

Figure 1. Location of sites at Tiparra reef, South Australia.

emergent abalone encountered was tagged, during systematic searches of the areas. After tagging was completed all untagged emergent abalone in treatment areas were removed. The size of density-reduced areas was approximately three times larger than control areas to ensure similar numbers of tagged individuals after thinning.

Recapture surveys also involved systematic searches of each area, but when aggregations were encountered, the numbers of tagged and untagged abalone were counted. At each site the original density was estimated using the number tagged in March, and the final density in September was calculated from both the number recaptured and the proportion of tagged to untagged abalone in aggregations during the recapture surveys. This latter density estimate assumed that the proportion of tagged individuals within the aggregations measured reflects the proportion of tagged to untagged individuals in the remainder of the area. An aggregation was defined as a group of abalone with no more than 150 cm between two individual abalone, a key distance for fertilization success of *H. laevigata* (Babcock & Keesing 1999). A high proportion of abalone were in aggregations at all sites. Only abalone found in their area of origin were included in the abundance estimation.

Each site varied in degree of aggregation as well as habitat. The "Lighthouse" site was at 3-m depth, with smaller aggregations of abalone that were relatively evenly distributed on continuous limestone habitat. The "Aggregation" site consisted of small to large aggregations of tightly clustered abalone at 6-m depth. Aggregations were found on patches of flat limestone reef among seagrass. The third site, "Sand Gutters," also at 6-m depth, was established among parallel gutters of limestone reef in between raised ridges of sand. The dominant seagrasses at each site were *Posidonia* spp., but there were small patches of *Amphibolus antarctica* and a variety of macroalgae. Although the sites varied greatly in habitat, few abalone in each area reached the legal minimum size (130 mm), and their densities were consistently high prior to thinning. Commercial abalone divers reported that these areas were rarely fished because large abalone were always scarce.

For the translocation experiment two sites where abalone grew to large sizes were established approximately 1 km from the "stunted" sites. Both these sites contained abalone at densities and sizes typical of productive commercial fishing grounds, with an average size approximately 15 mm larger than the slow growth sites. Commercial divers had not fished at either fast growth site for at least 3 y. These sites were surrounded by luxuriant stands of *Posidonia* spp. and *Amphibolus antarctica*, with a large loading of epiphytic algae (suitable greenlip food) during surveys in March and September.

Abalone were removed from each fast growth site and a proportion was tagged on the boat and returned to the bottom as fast growth controls. The remainder were removed from the site to allow the translocation of tagged abalone from slow growth sites while maintaining the original density of abalone at the site. Densities of abalone at the two fast growth sites approximated those of slow growth sites. Abalone removed during thinning of the areas at the Lighthouse and Aggregation sites were tagged at the surface and translocated to Fast Growth Sites 1 and 2 respectively. Surface exposure times were similar for all treatments. At the fast growth sites similar numbers of treatments and control abalone were mixed within the same habitat. A second control area was established at each of the Lighthouse and Aggregation sites. Abalone were removed from the bottom and tagged at the surface before being returned, to replicate the method of tagging for transplants and at the fast growth sites.

Abalone were recaptured and measured from each area in September. Incremental growth was standardized to 180 days and regressed against the release length. Because growth increment is expected to vary with initial size, size was included as a covariate, and size-specific responses to treatments were expected. Because Shepherd and Hearn (1983) found growth differences between sexes at one of the sites they investigated, initial ANCOVAs for each site and treatment were set up to test whether growth varied between the sexes. Because we did not detect significant differences between sexes ($P > 0.05$), the data were pooled for subsequent analyses. Wells and Mulvey (1995) also found no significant differences in growth rate between sexes for *Haliotis laevigata* in Western Australia.

ANCOVA assumes the covariate is similarly distributed between treatments (Quinn & Keough 2002). In the thinning experiment only data from the Aggregation site contained a different range of sizes for the two treatments. Trimming the data to contain only individuals greater than 90 mm made no difference to the significance of the test and therefore the data from the thinning experiment were not trimmed. In the analysis of the translocation experiment the data were trimmed to include only abalone between 80 mm and 160 mm, to ensure all treatments extended over the same range of sizes. We checked whether the relation of growth increment to initial length was linear by plotting the mean increments of 10-mm size classes. Confidence intervals were calculated for asymptotic lengths (the X axis intercept) from each regression using formulae for X axis intervals in Snedecor and Cochran (1967).

RESULTS

At the Aggregation and Sand Gutters sites the densities remained similar over the 6-mo period; at the Aggregation site density was reduced from 33% of original density after thinning to 29% in September, and at the Sand Gutters site it increased slightly

TABLE 1.

Estimation of abundance from the proportion of tagged to untagged individuals encountered within sites at Tiparra reef.

Site	Treatment	March Abundance	Number Tagged	% Abundance Post-thinning	Total Tags Recaptured	% in Aggregations with Tags	Estimated September Abundance	% of March Abundance
Lighthouse	Thinned	603	201	33%	74	19%	389	65%
	Control	246	246	100%	99	51%	194	79%
Aggregation	Thinned	810	270	33%	142	61%	233	29%
	Control	269	269	100%	215	81%	265	99%
Sand Gutters	Thinned	354	118	33%	85	67%	127	36%
	Control	135	135	100%	97	93%	104	77%

from 33% to 36% (Table 1). The Lighthouse site showed an increase in density consistent with some degree of immigration, from 33% after thinning to 65% after 6 mo (Table 1). The proportion of tagged to untagged individuals reduced from 100% to 19% 6 mo later, and only 37% of all tagged abalone were recaptured within the area. Nevertheless, the average density (the mean of 33% after thinning and 65% after 6 mo) is approximately half of the original abundance. Control area densities remained about the same at the Aggregation site but reduced slightly at the Lighthouse and Sand Gutters sites. At these two sites the average decrease in density was only 10% after 6 mo.

Analysis of covariance was performed using data from each of the three sites. The treatment by length interactions were significant; that is the slope of growth rate versus length differed between the control and thinned areas, at each site (Table 2). These tests produce conclusions that relate to each site and might be due to chance differences between the two areas. Sites were then used as replicates to test the effects of density reduction. The treatment by length interaction was tested against the 3-factor interaction because sites were a random factor. This test was significant ($F = 67.969$ $df = 1, 2; P < 0.05$), and we conclude that thinning changes the relation between size and growth.

At all sites smaller abalone showed more rapid shell growth in response to thinning (Fig. 2). The size-specific rates of growth at the Aggregation and Sand Gutter sites were similar when compared between control areas and between thinned areas. At the Lighthouse site however, growth rates were much higher, such that size-specific growth at the Lighthouse control was similar to growth in the thinned areas at the other two sites. Nevertheless, the magnitude of the difference between treatments and controls at any given length was very similar at all three sites. The asymptotic lengths of the abalone (X axis intercept) were similar at all sites

and treatments, except for the controls at the Aggregation site (Table 3).

The translocation experiment data were analyzed separately for each site as fast growth control versus translocated and slow growth control versus translocated (Table 4). In analyses of covariance for the translocated versus slow growth controls the treatment by length interaction was highly significant at the Aggregation site (Table 4) but not at the Lighthouse site, probably because there were only 46 recaptures at the Lighthouse slow growth control site. There was, however, a highly significant difference between thinning treatments at the Lighthouse site (Table 4). For translocated versus fast growth controls there was no significant treatment by length interactions, so this interaction term was omitted from the model. In both cases there were highly significant differences between treatments (Table 4). No analysis using sites as replicates was performed because there were only two sites in the experiment.

For translocated abalone from both the Lighthouse and Aggregation sites, the patterns of growth were consistent (Fig. 3). Translocated abalone responded in a similar manner to thinned abalone when compared with slow growth controls, with smaller abalone showing more rapid growth in response to the change of habitat, whereas there were no significant differences in asymptotic length (Table 5). When compared with fast growth controls, translocated abalone grew at a consistently slower rate across all lengths (Fig. 3), resulting in significant differences in asymptotic length at both sites (Table 5). Once again the magnitude of the response in both cases was similar, despite differences in growth rates between the sites.

DISCUSSION

The growth differences between thinned and control areas were consistent at all three sites despite differences in the magnitude of the density reduction. There were indications of substantial immigration leading to increasing density within thinned areas after 6 mo at the Lighthouse, but not at other sites. There was minimal cryptic habitat and therefore emergence was not likely to have contributed to the increase in density. Presumably, abalone migrated into the area because of the relatively greater abundance of food. At both the Lighthouse and Sand Gutters sites a small reduction in the abalone density within control areas, only 10 m away, was observed. Officer et al. (2001) obtained identical patterns of movement and reaggregation during density reduction experiments of blacklip abalone, and they suggested that the reduction in density within control areas was an indirect consequence of redistribution of individuals into the thinned areas. Be-

cause of the closeness between control and treatment areas in our experiment, decreases in control density may also have been a consequence of movement into thinned areas, but we did not find any tagged controls in thinned areas.

We expect that tag loss was minimal over our 6-mo experiment, but note that because we estimated final density from the number tagged and the proportion of tagged to untagged during the recapture dives, tag loss would not have affected our density estimates. Mortality of adult abalone over 6 mo would be expected to be very low. The average density over 6 mo at the Lighthouse site was 50% of the original density in the thinned areas and 90% of original density in control areas, effectively equating to a 40% reduction. The average density reduction at the Aggregation and Lighthouse sites were 70% and 60% respectively. Despite the extent of

movements at the Lighthouse site, an average density reduction of only 40% was sufficient to establish significant differences in growth rate between thinned and control areas, comparable with the other two sites.

The consistent differences observed led to the overall test result: that density reduction led to an increased slope of the increment versus length regression. The slope of these regressions reflects the Von Bertalanffy growth parameter k , and the X intercept approximates L_{∞} (Day & Fleming 1992). It is clear that for slow growing populations of greenlip abalone, density reduction increases k , but in general it seems not to change L_{∞} much, at least in the short term. This response may reflect the preference of juvenile abalone to direct extra resources into shell growth, whereas larger, older individuals may be placing more of these resources into maintenance and reproduction, a trade-off common to many species (Stearns 1992). L_{∞} was significantly greater in the control area at the Aggregation site than at all other controls and treatments. This difference may be a consequence of the relatively small number of large abalone in the thinned treatment at this site.

At the fast growth sites, a greater food supply was clearly evident during both March and September, because areas of adjacent seagrass had much larger epiphyte loads compared with slow growth sites. These differences in food availability presumably led to the differences in growth and asymptotic length between slow growth and fast growth controls.

We hypothesized that individuals exposed to the same food supply should respond similarly in regard to growth regardless of their growth history. Abalone translocated from slow growth to fast growth sites obtained the same k as the fast growth control population, reflected in the parallel lines of regression at both sites, but grew at a consistently slower rate for all sizes and so that there was a significantly smaller L_{∞} . This suggests that the growth history of an individual does not affect its future k but will affect its maximum size. This difference in average L_{∞} might be expected if there is an age effect on growth, given that slow growing individuals at any given size are likely to be older than fast growing abalone of the same size. An alternative hypothesis is that the previous history of abalone determines their resource allocation, so that the larger transplanted abalone may devote almost all of the resources they have available beyond maintenance requirements, to reproduction. It would be useful to study changes in growth and fecundity over longer periods to see if this pattern persists.

Direct comparison of translocated abalone with the thinning experiment controls could not be made because the latter were tagged in situ. Translocated abalone had to be handled on the boat so all controls were treated in the same way. When the growth of translocated abalone was compared with slow growth controls, the

pattern of growth response was the same as for thinning and was similar among sites. On the basis of these results it is reasonable to speculate that the manipulation of density reduction and change of habitat have increased the quantity of food available to the individuals within that population, and this led to the size-specific growth response seen in both experiments over the short periods of this study.

The magnitude of the response in shell growth to the density reductions of 40% to 70% in unfished populations is critical for stock assessment. Many biomass dynamic fishery models have adopted sustainability criteria such as failure to maintain a mini-

mum proportion of original biomass, to trigger management intervention. For these triggers the values used are usually around 40%, equivalent to a loss of 60% of the original unfished biomass (Smith & Smith 2002). For abalone, Shepherd & Baker (1998) suggested that a minimum egg production of 40% to 50% be maintained. Depending on size limits, these values are likely to equate to density reductions within the range of this study. Thus it is important that assessments of areas are not carried out soon after a small area is fished. The magnitude of the density dependent growth response we observed, despite the short-term nature of our experiment, suggests that biomass reduction of legal sized abalone by fishing would be at least partly compensated by growth over longer periods.

In the longer term, density dependent growth would accelerate stock declines in fisheries with a legal minimum length (LML), because fishing would increase the growth rate of sublegal sized abalone, rendering them vulnerable to fishing after a shorter period of time. Density dependent growth becomes compensatory however, when the increase in size reduces mortality or increases fecundity (Rose et al. 2001). For *H. laevigata* there is clear evidence of both size dependent mortality (Shepherd & Breen 1992) and rapidly increasing fecundity with increasing size (Shepherd et al. 1992). Therefore the significant increases in growth rate that we observed could be expected to act as a regulatory mechanism that promotes increased population growth to compensate for losses caused by density reduction.

McAvaney et al. (this volume) have shown that juveniles at low density will reach larger sizes and mature earlier than juveniles at high density. Their study involves the manipulation of densities of

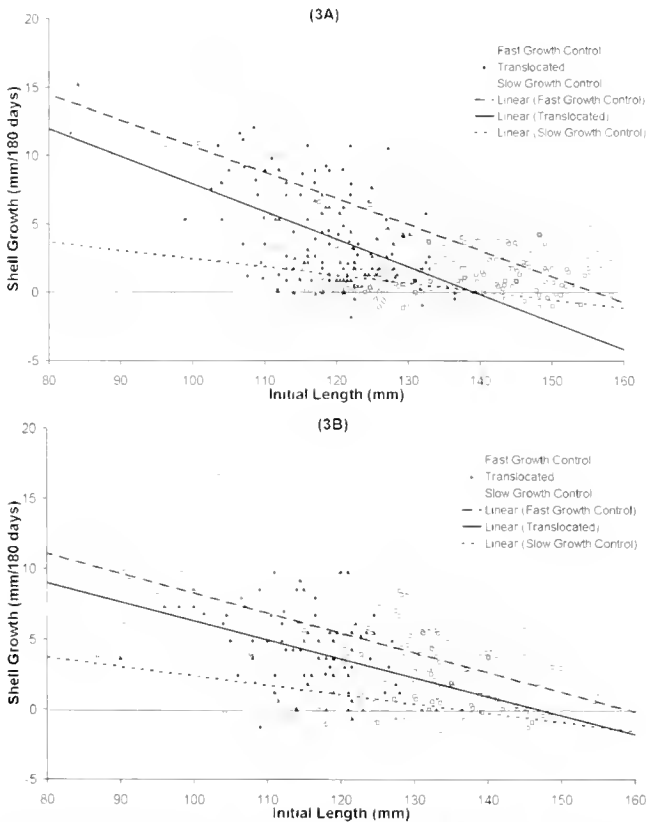

Figure 3. Regression of growth increment versus initial size for relevant fast and slow growth control populations compared with abalone translocated from the (A) Lighthouse site and (B) Aggregation site.

TABLE 5.

Estimated asymptotic lengths and confidence intervals based on regressions of control and treatment data at each site of the translocation experiment.

	Slow control	461	133.4	137.6	141.7

juvenile greenlip abalone (<90 mm) outplanted into the wild. It is important to determine whether a reduced density of adult sizes leads to faster growth of juveniles that occupy more cryptic habitats and thus might be more affected by juvenile than by adult density.

In our study we have shown that compensatory growth will occur in fished abalone populations. We hypothesize that larger abalone were allocating extra resources into reproduction and that if this were the case, further compensatory effects would occur. If fishing large adults leads not only to faster growth of small adults but also to faster recruitment of adults from the juvenile size classes, then these mechanisms in combination may assist to stabilize adult stocks against the impact of fishing and at least partly maintain the egg production capacity of abalone populations, which will in turn increase prospects for their sustainability.

ACKNOWLEDGMENTS

The authors thank the Central Zone divers and deckhands of South Australia for their contribution in the field; Michael Tokley and Bob Pennington for administrative assistance; Sylvain Huchette for the very valuable assistance in experimental design and lead role in fieldwork. The authors also thank Harry Gorfine and Matt Reardon for constructive criticism of the manuscript; Scoresby Shepherd, James Brook, Simon Hart, Matt Reardon, Thor Saunders, Steven Mayfield, and Brian Davies for their assistance in field work. This research was conducted as a component of a project established between the University of Melbourne and the Abalone Industry Association of South Australia, funded under the Australian Research Council (ARC) Strategic Partnerships with Industry Research and Training (SPIRT) Scheme

INFORMATION FOR CONTRIBUTORS TO THE *JOURNAL OF SHELLFISH RESEARCH*

Original articles dealing with all aspects of shellfish research will be considered for publication. Manuscripts will be judged by the editors or other competent reviewers, or both, on the basis of originality, content, merit, clarity of presentation, and interpretations. Each article should be carefully prepared in the style followed in prior issues of the *Journal of Shellfish Research* before submission to the Editor. Papers published or to be published in other journals are not acceptable.

Title, Short Title, Key Words, Abstract: The title of the paper should be kept as short as possible. Please include a "short running title" of not more than 48 characters including spaces, and key words. Each manuscript must be accompanied by a concise, informative abstract, giving the main results of the research reported. The abstract will be published at the beginning of the article. No separate summary should be included.

Text: Manuscripts must be typed double-spaced throughout on one side of the paper, leaving ample margins, with the pages numbered consecutively. Scientific names of species should be underlined or in italics and, when first mentioned in the text, should be followed by the authority. Common and scientific names of organisms should be in accordance with American Fisheries Society Special Publications 16 and 17: *Common and Scientific Names of Aquatic Invertebrates from the United States and Canada: Mollusks and CSNAIUSC: Decapod Crustaceans*, or relevant publications for other geographic regions.

Abbreviations, Style, Numbers: Authors should follow the style recommended by the sixth edition (1994) of the *Council of Biology Editors [CBE] Style Manual*, distributed by the American Institute of Biological Sciences. All linear measurements, weights, and volumes should be given in metric units.

Tables: Tables, numbered in Arabic, should be on separate pages with a concise title at the top.

Illustrations: Line drawings should be in black ink or laser print and planned so that important details will be clear after reduction to page size or less. No drawing should be so large that it must be reduced to less than one third of its original size. Photographs and line drawings should be prepared so they can be reduced to a size no greater than 17.3 cm × 22.7 cm, and should be planned either to occupy the full width of 17.3 cm or the width of one column, 8.4 cm. Photographs should be glossy with good contrast and should be prepared so they can be reproduced without reduction. Originals of graphic materials (i.e., line drawings) are preferred and will be returned to the author. Each illustration should have the author's name, short paper title, and figure number on the back. Figure legends should be typed on separate sheets and numbered in Arabic.

Digital Figures: Authors may provide digital figures (they are not required); they must be accompanied by hardcopy figures of equal quality, which the printer will use for comparison and backup. If digital figures are supplied, please note the following instructions:

- Each piece of art should be saved as its own file.
- Files must be one of the following formats: TIF, EPS, or JPG.
- Each file should be named according to its figure number and format (e.g., "fig2b.tif").

- Figures must not be embedded in a word-processor or spreadsheet document: the printer cannot use images stored in Word, WordPerfect, Excel, Powerpoint, etc.

- Resolution: *line shots:* 1000 dpi; *halftones/grayscale:* 300 dpi if no lettering, 500 dpi if figure contains lettering.

- Color figures: save the files as CMYK-encoded TIF images (preferred) or CMYK-encoded EPS or JPG images. Color figures have the same resolution requirements as B/W, above.

Color illustrations will not be accepted unless the author agrees to cover the cost of associated reproduction and printing.

Literature Cited: References should be listed alphabetically at the end of the article. Abbreviations in this section should be those recommended in the *American Standard for Periodical Title Abbreviations*, available through the American National Standard Institute, 1430 Broadway, New York, NY 10018. For appropriate citation format, see examples below:

Journal:
Watts, R. J., M. S. Johnson & R. Black. 1990. Effects of recruitment on genetic patchiness in the urchin *Echinometra mathaei* in Western Australia. *Mar. Biol.* 105:145–151.

Chapter in Edited Book:
Davio, S. R., J. F. Hewetson & J. E. Beheler. 1985. Progress toward the development of monoclonal antibodies to saxitoxin: antigen preparation and antibody detection. In: D. M. Anderson, A. W. White & D. G. Baden, editors. Toxic dinoflagellates. Amsterdam: Elsevier. pp. 343–348.

Page Charges: Authors or their institutions will be charged \$100.00 per printed page. All page charges are subject to change without notice. A handling fee of \$60 will be charged for all manuscripts accepted for publication.

Proofs: Page proofs are sent to the corresponding author and must be corrected and returned within seven days. Alterations other than corrections of printer's errors may be charged to the author(s).

Reprints: Reprints and PDF files of published papers are available at cost to the authors. Information regarding ordering will be available from The Sheridan Press at the time of printing.

Cover Photographs: Appropriate photographs may be submitted for consideration for use on the cover of the *Journal of Shellfish Research*. Black and white photographs and color illustrations will be considered.

Corresponding: An original and two copies and electronic copy of each manuscript submitted for publication consideration should be sent to the Editor, Dr. Sandra E. Shumway, Department of Marine Sciences, University of Connecticut, 1080 Shennecossett Rd., Groton, CT 06340. E-mail: sandra.shumway@uconn.edu or sandrashumway@hotmail.com

Membership information may be obtained from the Editor or the Treasurer using the form in the *Journal*. Institutional subscribers should send requests to: *Journal of Shellfish Research*, P.O. Box 465, Hanover, PA 17331.

THE NATIONAL SHELLFISHERIES ASSOCIATION

The National Shellfisheries Association (NSA) is an international organization of scientists, management officials and members of industry that is deeply concerned and dedicated to the formulation of ideas and promotion of knowledge pertinent to the biology, ecology, production, economics and management of shellfish resources. The Association has a membership of more than 1000 from all parts of the USA, Canada and 18 other nations: the Association strongly encourages graduate students' membership and participation.

WHAT DOES IT DO?

- Sponsors an annual scientific conference.
- Publishes the peer-reviewed *Journal of Shellfish Research*.
- Produces a Quarterly Newsletter.
- Interacts with other associations and industry.

WHAT CAN IT DO FOR YOU?

- You will meet kindred scientists, managers and industry officials at annual meetings.
- You will get peer review through presentation of papers at the annual meeting.
- If you are young, you will benefit from the experience of your elders.
- If you are an elder, you will be rejuvenated by the fresh ideas of youth.
- If you are a student, you will make useful contacts for your job search.
- If you are a potential employer, you will meet promising young people.
- You will receive a scientific journal containing important research articles.
- You will receive a Quarterly Newsletter providing information on the Association and its activities, a book review section, information on other societies and their meetings, a job placement section, etc.

HOW TO JOIN

- Fill out and mail a copy of the application blank below. The dues are 75 US \$ per year (\$35 for students) and that includes the *Journal* and the Newsletter!

NATIONAL SHELLFISHERIES ASSOCIATION—APPLICATION FOR MEMBERSHIP
(NEW MEMBERS ONLY)

Name: _____ For the calendar year: _____ Date: _____

Mailing address: _____

Institutional affiliation, if any: _____

Shellfishery interests: _____

Regular or student membership: _____

Student members only—advisor's signature REQUIRED: _____

Make checks (*MUST* be drawn on a US bank), international postal money orders or VISA for \$75 (\$35 for students with advisor's signature) payable to the National Shellfisheries Association and send to Nancy Lewis, Bookkeeper, PO Box 350, V.I.M.S. Eastern Shore Lab, Wachapreague, VA 23480, USA.
